NUMBER XLIX.

Frinted by JOHN NICHOLS, Red-Lion-Paffage, Fleet-Street, Londons

I. Specification of the Patent granted to Mr. William Charman, of Newcastle-upon-Tyne, Gentleman; for a Method of laying, twisting, or making Ropes or Cordage **.

WITH FOUR PLATES.

Dated Jan. 12, 1798.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said William Chapman do hereby declare, that my said new-invented method or methods of laying, twisting, or making ropes or cordage, of any number of yarns or strands, or any number of threads, tarred or un-

Vol. IX. B tarred,

^{*} This specification (for Scotland) contains the substance of two English patents, one granted September 13, 1797, the other March 6, 1798.

tarred, from the fize of a cable down to the Imallest line composed of more than one thread, is described in the several plans or drawings hereto annexed, and the following description thereof. It may occasionally dispense with the use of any or all of the following things or apparatus, made use of in the common method of laying ropes; that is to fay, a rope-ground, or fpace fufficiently long to ftretch out the yarn to make the rope or ftrand of the rope required, in which the yarns, thus extended, are twifted from one or both ends, by hooks to which they are attached, and which, being turned round their axes, twift the yarns in the mass through their whole extent, and form what the rope-makers call a strand; and so many of these strands as are requifite to form a rope, which are usually three, being joined at one end to the fame hook, and this being turned the contrary way round to what the hooks at that end were before, the three parts are thus twifted together, and form a rope; which is kept regular in its number of twifts. proportionate to its diameter and length, by a movable block of wood, called a top, with as many groves in it as there are strands. This top is held from turning round by a cross bar of iron, or of wood, and prevented from advancing too rapidly by pieces of rope, usually called tails, which are lapped round the rope that is making; and as, by the twifting of the yarns and of the rope, the length becomes shorter, the hooks to which the strands are fastened, (or that to which the rope is fastened,) being fixed upon an upright frame, on a movable platform, commonly called a sledge, advance forward accordingly.

This is the outline of the process usually purfued in making what is called a shroud-laid rope, each strand of which consists of a number of yarns twisted together; and if a cable or cable-laid rope is to be made, the common process is, to stretch out so many shroud-laid ropes as there are to be strands in the cable, (usually three,) and to purfue the same manner, in forming them into one rope, as in the preceding instance.

In the principal method which I pursue, those parts that separately twist the strands and rope (in place of being at the extreme ends of the rope and strands, and approaching each other as the rope shortens,) are at any determinate convenient distance.

The process of twisting, consequently, does not go forward through the whole length at once, but only in the intermediate space; and, in this instance, my invention consists in combining with that circumstance a mode of twisting the rope or cord itself by an arbor or shaft, perforated or open, through the whole, or a portion of its extent, and revolving round its own axis; and, at the same time, twisting its several strands or B 2 parts

parts by separate arbors or shafts, either perforated or otherwise; each shaft revolving round its own axis; and, by the aid of such other machinery as will be described, performing not solely the operation of twisting the rope or cord, but also that of coiling it up by the motion of the machine.

The process of twisting the rope, and that of coiling it up by the motion of the machine, necessarily keep pace with each other, and are performed by the same shaft; or, the coiling may, when more convenient, receive its motion from any other part of the machine. Each strand occupies another shaft, revolving only round its own axis, and containing, on one end of it, the yarns or threads, wound upon a reel or reels, or in any other manner.

This relates to the making of shroud-laid ropes; and, in the making of cable-laid ropes, the difference consists principally in giving the defcribed twiffing-shafts contrary directions to what they had before, and different proportionate velocities; and in coils of shroud-laid rope being substituted for coils or reels of yarn, for the forming of the strands.

On each of the shafts that turn the strands, these coils of rope are progressively uncoiling; and, at the shaft forming the rope, the other end is progressively coiling in sakes, or tiers of cable,

on a rotative platform; or, otherwise, round a reel moving round with the axis, twisting the rope or cable, but with a distinct axis of motion; or upon a reel that has the same axis of motion with the hollow tube or shaft that twists the rope; of each of which methods, one example is given in the plans. Besides which, my invention includes, as a principle, every other method of coiling up the rope or cord, or strand of a rope or cord, progressively, as it is made, by any motion from the machine or its moving power.

My invention confifts also in making a strand or cord, by treating each yarn or thread as a separate strand, in the manner already described; and consequently having as many yarn shafts as threads, all of which may be turned by a belt.

Left the principles I have described, which admit of confiderable variety in the execution, should not be sufficiently plain to enable any mechanic to construct a proper machine, I have annexed plans of one of the methods of application, both for shroud and cable-laid ropes, of which the following is an explanation.

In Fig. 1. (Plate I.) a, is a table or platform, with or without, as occasion may require, so many franchions b, b, as may be necessary to support the requisite number of reels of yarn; each reel turning round its own axis, as in ϵ , ϵ , in Figs. 1 and 2; and all the yarn concentrated at the head

of the shaft. The reels may also be placed in any other convenient manner, according to their number; and, if requisite, may be two or more tiers in height.

Of these tables, there are to be as many as there are designed to be strands in the rope: these tables or platforms I call strand tables; and each of them is to be fixed on a hollow shaft, capable of revolving round its own axis; which shaft I call a strand-shaft or an upper-shaft, and which is shewn by D, in Figs. 1 and 3.

The yarns composing a strand, or, in the case of cables, a strand itself, passes through this shaft, in which there is a transverse opening of fufficient width, which, in its best form, will be rather more than that of the longitudinal orifice. In the transverse opening, viz. between d and d, are to be inferted two blocks, d and d, (one on each fide,) of hard wood, or any other matter, with their oppofing faces, as circumstances may require, either longitudinally grooved, or flat, or concave, or otherwise; so as, when forced together by fprings, as fhewn in Fig. 1, or in any other manner, or by weights, as in Fig. 3, (Plate II.) or by any other means, they may fufficiently refift the paffage and twifting of the yarn or strand. These blocks should have their insidefaces rather bevelled towards the upper and lower ends: I call them press-blocks or compressors. Their

use,

use, in the making of shroud-laid ropes, is principally to give a resistance equal to the stress that would draw the sledge along, in the common method of making ropes; and, in cable-laid ropes, both to retard the passage of the strands, and prevent their turning round, and thus perform the part of the sledge itself, in the common method, and of the hook on its sace-board, or upright frame.

Those purposes, of holding the strand from turning round in the strand-shaft, and giving sufficient resistance to its passage through, I occasionally answer, by placing in the transverse opening two grooved rollers or sheaves d, d, Fig. 3, with axes large enough to occasion sufficient friction, and held together in the same way as the press-blocks: these I call the bolding-rollers, because of the office they are to perform. The holding-rollers may either move round their own fixed axes, or upon axes inserted through them, of sufficient diameter to occasion the necessary friction.

I also produce the effect of preventing the yarns from twifting round in the strand-shafts, by placing within, upon, or below each shaft, an attached block of wood, or plate of metal, or other substrance, with a number of notches or grooves round it, or perforated with a number of holes, through each of which, one or any number of yarns may be put: this implement I call a yarn-guide.

In small ropes, the yarn-guide, the holdingrollers, and press-blocks, may be dispensed with, and a pressure applied according to Fig. 10, (Plate IV.) or in any other manner, either upon the yarn itself, or upon the rim of the reel; the former being preserable only because it affords an uniform resistance, notwithstanding the decrease of the diameter of the yarn on the reel.

The press-blocks and rollers may also be dispensed with, by a pressure upon the yarn or strand, at its entrance into the hollow-shaft, (or any where in its passage to it;) of which one example, out of the variety that may be adopted, is given in Figs. 11 and 12.

In Fig. 11, the yarn is stopped from going out too fast, by a pressure applied at u, which is farther explained by Fig. 12, which shews the plan of the table or frame fupporting the reel or reels. a, a, a, a, are the feet of the stanchions suftaining the reel. u, one fide of the shaft rifing above the platform, over which the threads pass, as at u, in Fig. 11, and are duly compressed by the clofing of the bar b b, the forks of which pass under the ends of u, in the opening shewn in Fig. 11: this bar is brought to its due preffure, by connecting it with the end of the fpring s s, and bringing it to its necessary degree of tension. n, fhews the hole down the shaft, through which the threads pass. If the number of yarns be very few. few, or divided into feveral parcels, it will be necessary to place, between the bar and the part it presses against, a kind of collar (round the thread or threads), of coarse woollen cloth, leather, felt, or other substance, which may also be applied various ways in the longitudinal grooves of the press-blocks, so as to occasion an equable resistance to the yarns in each groove.

These methods may also be used for as many individual yarns as form a strand; and motion may be given to any number of reels, by a belt round the wheels g, g, Figs. 10 and 11.

It is perhaps barely necessary to say, that one press-block, or one holding-roller, may be made to answer the proposed end, by making the transverse opening to pass through only one side of the tube in the strand-shafts of Figs. 1 and 3; and that the tables or frames containing the reels, &c. may be placed or fixed to any part of the strand-shafts, and even on their bottom: in which case, these shafts need neither be perforated, nor open on one side, as the strands or yarns would neither have to pass through or along them, but only to be compressed, so as to prevent their either twisting, or passing off safter than requisite.

The strand-shafts all turn uniformly the same way with each other, by means of an upright shaft C, and wheel 6, communicating with a Vol. IX.

C wheel

wheel g on every strand-shaft, as described in Figs. I and 3, or by any other means. These shafts are placed as close to each other as they conveniently can: and the strands from the ends of each are all concentred to a proper point, and brought to a fixed unrevolving block of wood, or other substance, of a conic or other form, and with as many, grooves, holes, notches, or guides, as strands in the rope, to answer the end of the top in the common method of laying ropes, which end also may be produced by pulleys, sheaves, or any other guides.

This block b, I call the laying-block. Between it and the yarn-guide, the holding-rollers, or the press-blocks, (according as they are used,) all the strands receive their proper twist; and below it (the same as between the top and the single hook, in the common method of laying ropes) they unite, and become a complete shroud-laid or common rope, by the turning of the shaft immediately below the laying-block, viz. E, which I call the rope-shaft or lower-shaft, and which, by its apparatus, performs the part of the single hook at the end of the rope, in the usual method.

Between the rope-shaft and the laying-block, I occasionally place a short hollow cylinder of wood, or metal, viz. i, of the size of the rope to be made; the head of this may be trumpetmouthed, to receive the lower end of the laying-

block.

block. In this cylinder (which, for ease of placing, may be composed of two parts) the strands first unite, and become a rope.

The rope-shaft is perforated, or open in its upper part, and has no prefs-blocks or holdingrollers to retard the progress of the rope, but, on the contrary, a pair of theaves or wheels moving eafily on their axes, to admit the rope a free paffage, and, at the fame time, compel it to twift equally round with the shaft. These sheaves or wheels, which ought, like the holding-rollers, to be grooved in fuch a manner as to hold the rope from turning fideways, I call the twisting-sheaves. Between thefe and the hollow cylinder, I occafionally infert, in the head of the rope-shaft, hollow tubes of metal, or other fubftance, fuited to the fize of the rope, which I call gauge-tubes. When proper gauge-tubes fill up the space between the cylinder and the twifting-sheaves, the latter may be forced round, by the action of the rope pushing from the laying-block, in the fame manner as the top in the common method is forced onwards, notwithstanding the great resistance made by the tails or tail-ropes. But, in other instances, these twisting-sheaves may receive such a progreffive motion as, in every revolution of the rope-shaft, (which makes one turn of the rope,) the groove of the sheave shall move such a space as may be equivalent to the length of rope that is defigned C 2

defigned to be made by every turn, which will be in proportion to its diameter; and also accordingly as the rope is defigned to have more or less twift, or, in the usual phrase, be long or fhort laid. A method of performing this will be feen by Fig. 3, and is described in the explanation of the rope-shaft of that plan, and its appendages. The rope, from below these twistingsheaves, passes out so far made, and, amongst other methods, is difposed of in the following ways. If not too unwieldy, I coil it upon a reel, as at m, in the rope-shaft E of Fig. 1, which is more particularly described in Figs. 4 and 5, (Plate III.) and in their explanation; where it is shewn, that ropes of different fizes may be made to coil upon the reel, fo closely as to require tying up only, and thus fuperfede the necessity of any farther operation.

For the making of all ropes thus coiled upon a reel, either weights or fprings may be made use of to tighten the twisting-sheaves, and the press-blocks or holding-rollers; and consequently the position of the shafts may be in any direction at will, whether horizontal, vertical, or oblique, the axes all pointing the same way, or nearly so; the best position being for the strand-shafts to concentre a little towards the head of the rope-shaft. The strand-shafts and tables may either stand round one common centre, as in Fig. 2, which

which will in general be the most convenient for ropes; or they may stand side by side, in a right line, or with such a degree of curvature as may accord with the number of sets that may be moved by one great wheel or belt; which latter mode will be the most convenient for small lines and cords, and also for small ropes. The ropes that are too large to coil upon a reel, I coil upon a rotative platform, as in Fig. 3. FF, which is sully described in the explanation of the rope-shaft of that sigure, and its appendages.

The outlines of making shroud-laid ropes being now made apparent, there remains to be fhewn the process for making cables or ropes of that description. It confifts, as above, in strand-shafts and a rope-shaft; the principal difference being, that they are to move contrary ways to what they did before, and make a fimilar, or nearly fimilar, number of revolutions, in place of the confiderable disparity of twifts that are requisite for the strands of the rope itself, when laid as a shroud. This disparity admits of variety, from the causes I shall afterwards mention; but, for the purpose of explanation, I shall at present assume it at two to one in three-strand ropes (which is nearly the average). and then the proportionate revolutions of the rope and strand-shafts should be three to one, because every revolution of the rope-shaft takes out one twift from the strands.

If the yarns be fo hard twifted as to have more than their due proportion of counterbalance to the untwisting tendency of the strands, then the proportionate twifts of the rope may generally be less than I have stated: but, if the yarns be unable to refult the untwifting of the strand, or even be twisted the same way as the strand, which frequently is the case in common ropes of a small number of yarns, then the twifts of the ropes to those of the strands should be more than I have ftated: what they precifely should be, can be no object of this patent; and I only observe, that a finall deviation, on either fide of the proportionate number of turns of the rope, will be attended with no inconvenience but what will be remedied on its being stretched and used a short time, when it will affume that proportionate twift which will balance the counteracting power of the ffrand.

From these circumstances it follows, that cablelaid ropes must either be made on separate machinery, or the shafts must assume contrary turns, and different proportions, to what they had before; means of doing which will be described in the explanation of the rope-shaft of Fig. 1.

If the cable-laid rope be fmall, fo that its ftrands were made upon reels, as at m, in the rope-fhaft of Fig. 1, then thefe reels, as they come from the rope-fhaft, may be fixed upon ftanchions,

stanchions, as the yarn-reels at c, c, on the strandtables of Figs 1 and 2: or, as must be the case in large ropes, they may be laid on the upper tables in coils, as at c, on the strand-table of Fig. 3, and their ends passed through the strandshafts, and united below the laying-block, and brought down between the twisting sheaves n, n: a short piece of rope being then attached to their ends, and brought out of the opening below the sheaves, and passed over the coiling-wheel p, and made saft to the coiling-stage FF, so as to draw it round, the whole process will go on as described in the explanation of the rope-shaft of Fig. 3.

According to my invention, when the rope is drawn forward by the twifting-sheaves, or other means, the top or laying-block and its appendages may be dispensed with; because, at some given point, according to the proportionate twists of the threads or strands to those of the cord or rope, the rope and its strands, or the cord or line and its threads, will balance themselves. If the strand or yarn shafts be set so some a wide angle with the head of the lower-shaft, the point of junction will be at the head of that shaft; but, if the strand-shafts form an acute angle from their feet to the head of the lower-shaft, then the point of concentration will be above the head of the latter; and no very material inconvenience

will even then arise, provided the pressure retaining the separate strands or threads be quite equal; but, if otherwife, the rope or cord will appear with a ftrand higher or lower than the rest, accordingly as it may be longer or shorter, by receiving too little or too much refisfance in passing from its shaft; which refistance may be regulated, on stopping the machine, by flackening or tightening the fprings shiewn in the upper shaft of Fig. 1, or by moving inwards or outwards the weights upon the levers, as shewn in the uppershaft of Fig. 3; and may also, if thought necesfary, be regulated, during the going of the machine, by occasional pressure applied on a collar connected with the lever, and capable of fliding up or down any proper part of the shaft.

What I have called shafts, are, under this denomination, principally applicable to the manufacturing of rope; and, when suited to the making of cord, they will be more properly denominated 'spindles, which of course must be understood through the whole description; and, what I have called upper and lower shafts, will, in the application to cord, be upper and lower spindles.

In the lower-spindles, and even in the lower-shafts for small ropes, there will be no necessity for any part of them being perforated, or open, provided the spindle or shaft be retained in its position, by collars below the reel on which the cord or rope winds up as it is made.

My invention likewife confifts in making the strands separately, in the following manner: that is to fay, I coil or wind up the yarn requifite for a strand on one reel, or any number of reels or bobbins, and fix the reel, or reels or bobbins, on a pin or axis, or pins or axes, round or with which, it or they will revolve, as drawn off. The yarns are then twifted together, and drawn forward by a revolving shaft, similar to E in Fig. 1 or 3, placed in any requifite position, (to which shaft the reels are not fixed:) the yarns are thus made into a ftrand, which is coiled up, during the process of making, in the modes herein described, or in any other manner, fo as to admit of the revolution of the axis or shaft making the strand; which, when thus made, may either be treated fimilar to a cable-ftrand, as already described, or it may, with other strands, be laid in a common rope ground, or after the common method, as may also the strands made by any other of my processes, my method being to complete the rope after any of those ways, according to circumstances. In this method, of making the ftrand by drawing the yarns or threads from off separate reels, that are not fixed to the revolving axis, or fhaft that twifts the threads together into a strand, I regulate the coming forward, or making of the strand, by apparatus fixed to, or connected with, the shaft, either in a manner similar to what VOL. IX.

what is explained in the description of the shafe and apparatus for twifting the strands into a rope, or in any other way. I also place above, or leading to, the head of the shaft, a yarn-guide, to separate the yarns to any extent deemed necessary, likewise to enable them to come off in greater or less quantity, as required by the part of the ftrand they fall into. I regulate the refistance to their coming forward, to any extent wanted to give fufficient compactness to the strand, and, at the same time, not prevent the yarns from any reel, or number of reels, from coming forward as required; for this purpose, that refistance may either be placed on the reels themselves, or in any manner that separates or divides the whole mass of yarns, or in any other way that allows one or more yarns to flip or come forward independently of the rest.

By the method previously described for making a complete rope at one operation, I, during the act of making the strands, unite them into a rope, by means of what I there call a rope-shaft, in which they are all concentred, and receive the twist which forms them into a rope: but I also occasionally omit the concentring of them, and the subsequent part of the operation, during the making of the strand or strands, and, in place of twisting them into a rope, I only draw the strand forward, as made, and coil it or them in any manner what-

foever; they, in this inftance, having no rotative motion. The apparatus for drawing forward is not fixed to the revolving-shaft, containing the reel or reels, and other necessary appendages, but may be permanent, and receive its motion in any proportion whatever to the revolutions or twists given to the strand by that shaft.

The principles of making the strand in these two different ways are obviously portions of the process that would, as has been described, make the whole rope at one operation; and those two methods of making the strand, independently of making the complete rope, are reducible to the following principle; that, in making a strand simply, one end only need to be twisted, and the other held from turning, but that both be permitted to pass forward, and progressively change place; and that the yarns be, if deemed necessary, so regulated as to come off their reels in such a manner as the part of the strand they come into may require.

There is also a third method of making a strand, compounded of the two preceding, which may be followed, viz. that of using two revolving shafts in place of one; the reels being placed on one of them, and the strand coiling upon the other: these two shafts ought to turn in contrary directions to each other, in place of going the same way about, as they do in making the strands and rope at the same process.

The

The making of an individual frrand is particularly useful, when the rope-machine, explained in Figs. 1 and 2, is not fufficiently large to make the rope required; under which, or in any other predicament, I occasionally fix the requisite number of reels on the strand-tables, shewn in Fig. 2, and, paffing the yarns through the upper-shafts, in the lame manner as if a rope were going to be made, I unite them at the head of the lowershaft E; and then, in place of the fixed layingblock b, which is used in the making of ropes, I fix a yarn-guide, with any number of grooves or openings, fuited to the number of yarns, or any division of that number, and then the process goes forward as in the making of a rope, with this difference, that the upper tables stand still: this method differing in nothing, from one of those afore-described, but in the saving of the distinct apparatus that would be requisite, to refift the paffing off of the yarns, and to give the necessary hardening or compactness to the strand.

Besides these methods of separately making strands in such a manner as to give every yarn, or determinate number of yarns, their fair bearing in the strand, so as to give it a degree of strength unattainable by the common process, I have invented a further method, which requires little more apparatus than is used in common roperies or laying-grounds, viz. at the head of the ropery,

or in any other part, I fix, upon pins, fo many reels as will contain all the yarns requifite for a strand, or the given number of strands determined to be made at one time, each reel containing one or more yarns; then, in the instance of making three strands, I fix to three different hooks, on the breast or fore-board of a sledge, so many yarns, feparately concentring to each other, as are requifite; the yarns being previously passed through the openings of three separate fixed tops or yarnguides, one opposite to, or correspondent with, each hook. Before, or on the face of each top, towards the fledge, there may or may not be fixed a cylinder, fuch as I have described below the laying block at the head of the rope-shaft. The yarns are then to be prevented from passing too eafily off their reels, either by a preffure on the reels themselves, or on the yarns, in their passage to, or upon, their feparate tops, or in any manner that will permit them to come off as wanted.

The men are then to heave upon, or turn round, the hooks of the fledge in the usual way; and the only remaining difference confists in the fledge being drawn progressively backward, as the strand is making, until the whole, or any determinate length of strand be made. The process of drawing backward may be done various ways; amongst others, by a rope to a capstan, moved either by a horse or men, according to the strength

ftrength requifite, which will not be confiderable, on account of the flowness of the motion of the fledge, which, although called technically by this name, I propose to move on wheels. The ftrands being now made, and all joined at one end by a fingle hook, the wheels of this sledge may either be locked, and itself laden with a proper weight, or it may have attached to it a common sledge, with its requisite load, and then the completion of the rope may go forward in the usual way.

By the described process of drawing the sledge backward, and by a single hook on the fore-board of the sledge, and a fixed top, or any thing equivalent to it, a rope may be made, during the process of making the strands, after that manner which I have described as admitting the strands to be coiled up in any manner whatever. The other method is, to wind up these strands during their making, and afterwards to stretch them on the rope-ground, previously to the commencement of forming them into a rope, and in this manner one large strand-machine would be sufficient.

I shall here observe, that, in place of reels of yarn, I occasionally substitute balls of yarn in canisters, or other vessels in which they may unwind.

The described shafts, machinery, and apparatus, are not limited to the form or position of which

which I have given, or shall give, descriptions, but obviously admit of great variety; and they may receive their motion from fteam-engines. from water, from wind, or from the power of animals, which may communicate the respective direction and velocity to the separate parts, by means of upright and lying shafts with cog-wheels, or by belts or chains, or any other methods, practifed by mill-wrights or others; my invention not confisting in any particular or limited mode of giving motion to the machine, but in all or any of the following things, viz. the application of a fixed unrevolving top or laying-block, of perforated or open strand-shafts, and of a rope-shaft; and in the use of hollow tubes or cylinders at the lower end of the top, and of gauge-tubes; and in using pressblocks or rollers, and sheaves or wheels pressed against the strand, or the rope, by weights, or by fprings, or any thing elastic or otherwise; the giving any determinate regular motion to the strand, or the rope, or cord or line, so as to give it any number of turns that may be defired in a given length; and in coiling up the strand, rope, cord or line, in any way, during the process of making it, by means of any machinery connected with that employment in making the strand, rope, cord or line, or with its movingpower; also in giving the contrary and differently proportioned motion to the same machine,

fo as to adapt it either to shroud-laid or cablelaid ropes or lines; and in such other particulars as will be more clearly described in the following explanations, or have been previously noticed, in which I include the placing of more reels or balls than one upon any single shaft, or revolving platform, used in the making of the strand of a rope.

In fine, my invention goes to the described methods or principles of twisting or laying; and (as a constituent part in the process of making,) that of coiling or winding up strands, ropes, and cords or lines.

And I likewise claim, as my invention, the application of rollers, which I call regulatingrollers, to the manufacturing of twine made of hemp, flax, or tow, the use of which rollers is to give any determinate number of twifts, in any given length of twine; for which purpose, they are to be intervening between the reels containing the separate threads of which the twine is composed; and the spindles making the twine, which (like the spindles used in the making of thread) must have belonging to each a flyer and a bobbin, the former twifting, and the latter reeling up, the twine as it is made; which it may do by its refistance to motion, from the friction of weights drawing or preffing against it, or other fimilar causes, and, by the effect of that friction,

it would draw the threads from off their reels, but it would be in a manner materially irregular, without conftant attention in increasing the weights, as the twine increased in thickness on its reel or bobbin. The use of the regulating-rollers therefore is, that the feparate threads shall pass from their reels between rollers that have fome given determinate motion to any number of turns in the spindle, and consequently be delivered precifely as wanted; for instance, if the twine be to have fifty turns in the length of one foot, then the faces of the rollers, between which the threads pass, must move one foot during fifty revolutions of the spindle; the mode of giving which proportionate velocity is unnecessary to be explained. as being known to every mechanic.

The reels containing the feparate threads composing the twine are put upon pins, or other axes, round or with which they separately turn, as required, to unwind. Their position is fixed, and their threads lead off to a conductor or opening, to guide them to the rollers; between which and the spindle, they receive their twist, and are formed into twine. I also claim, as my invention, the use of the regulating-rollers for the manufacturing of worsted, and likewise of cotton, yarns or threads, of any denomination, composed of more than one thread.

Explanation and Description of the Colling-Reel in Figs. 1, 4, and 5.

(See Plate I. and III.)

For ropes not exceeding four inches girt, (or as much more or lefs as may be found convenient,) I propose the lower shaft to be as in Fig. 1, where the two sides are spread out so as to receive a reel, which may receive its motion in the following manner.

On the end of the axis of one of the twifting fheaves n, (Fig. 1) may be affixed a pulley-wheel o. of the fame diameter; which, by means of a belt, may communicate with another pulley-wheel p, on the end of the axis of the reel on which the rope is to wind, and of the diameter of the part on which the rope begins to wind; confequently, as the twifting-sheaves move with the same velocity as the rope is laid, it will be capable of winding it up in the beginning; and, as the rope increases the thickness of the reel, the belt must slip in the proportion of that increase; or otherwise the pulley p, at the end of the axis of the reel, may be composed of two concentric wheels; the one so much less than the other, as to afford only a proper degree of friction to lay the rope tight on the reel.

- If wanted to wind regularly upon the reel, so as to fuperfede the necessity of coiling it again, the rope must pass through a collar, as at a, Fig. 5; and be guided from fide to fide, as each layer is completed, moving the width or diameter of the rope on every revolution of the reel; which may be effected in the following manner, as I shall exemplify in the coiling of a four-inch rope.

bc, in Fig. 5, is an iron bar, passing through the two fides of the frame holding the reel of the rope-shaft of Fig. 1. The end b is square, flat, or angular, and paffes through a fuitable hole, to prevent it from turning: the end c is a continuous fcrew, with its threads fo far diftant, that one revolution of the nut d, Figs. 4 and 5, or fome proportionate revolution of it, shall move the collar a the precise diameter of the rope; then, if the reel be fuited to take 12 turns of a four-inch rope on the length of its axis, the following explanation will be fufficient.

One revolution of the nut d, (which contains a female fcrew,) moving the collar a one diameter of the rope, and 12 diameters being equal to the length of the reel, the nut must reverse its motion at every 12 revolutions; then, if the nut d have eight teeth, and be in geer with the wheel e, of 32 teeth, which is on the same arbor with the pinion i, the latter will make one revolution, whilst the nut d makes four. The two wheels f

and g are constantly in geer with each other, and turn contrary ways; and, besides the teeth working into each other, and with the pinion h, they have, on the same axis with them, two half-wheels, (shaded black in the plan,) each of which have 24-teeth, that alternately work into the pinion i, of 8 teeth, and thus, giving three revolutions to it, give 12 to the nut d, which is the number required. It may be necessary to notice, that the wheels termed half-wheels, must be so much less than semicircles, as to prevent the possibility of both being in contact with the pinion i at the same time.

From what has been faid, it follows, that the wheel g only makes one revolution, during the time that the collar a moves backwards and forwards, and lays two complete layers of rope on the reel; which, in the prefent inftance of a four-inch rope, requires 24 revolutions of the reel, which, by the little pinion l, on the end of its axis, gives motion to the whole. If this pinion l have 16 teeth, and the wheel k four times as many, then the pinion k, on the fame arbor, having 8 teeth, and the wheels k and k teeth each, the latter must make only one revolution for 24 of the rope reel, which, in the prefent inftance, is the number required.

If the rope, in place of four inches girt, should only be three inches and three quarters, then, in place

place of the pinion l being of 16 teeth, another of 15 teeth is inferted on the end of the axis of the reel; and thus any rope, down to an inch and a half, or a pinion of 6 teeth, may, by the fame machinery, be closely coiled on the reel. In leffer ropes, lighter machinery may be used, and all the proportions of reeling be obtained, in a manner similar to that above described. m, is a screw, raising or depressing a collar in which the axis of the reel and the pinion l turns; so that, be the diameter of the latter increased or reduced, it may still be in geer with the wheel l.

Explanation of the ROPE-SHAFT of Fig. 3, with its Appendages, &c. Figs. 6, 7, and 8.

(See Plates II, III, and IV.)

E. The rope-shaft.

n n. The twifting-sheaves; one of which (being confined in its position) receives its progreffive motion from the endless screw o, on the axis of the small wheel r, which receives its motion by revolving against a fixed or stationary concave wheel s s.

Different velocities may be given to the twifting-sheaves, by having sheaves proportioned to the different ropes, as to the number of teeth in their periphery; having the greater number for •fpondent interval of thread, to fix upon the axis of the wheel r. I shall exemplify this in the instance of a 16-inch cable, which ought, if very hard laid, to come forward a foot, or a little more or less, in every revolution, and 16 inches, if rather slack laid.

Let the general proportion of the little wheel r be To of the fixed concave wheel ss, which it works within, and the teeth of the twifting-sheave as much more than an inch in their pitch, as the extremity of the fheave is beyond its griping point, then each revolution of the cable-shaft must lay a foot of rope, and so proportionately in all fmaller ropes, reducing the pitch or space between the teeth accordingly, viz. by increafing their number; and, in ropes of equal fize, decreafing their number, if defigned to be flacker laid. In the making of fmall lines or cords, both these wheels may be dispensed with; as the twifting-sheaves may then bear such a proportion to the diameter of the line or cord, that one tooth of that sheave may be equal to the length of line or cord made by one revolution of the lower shaft or spindle; and, consequently, a fixed wheel, containing an endless fcrew of one thread, equal to the space (and vacancy) of a tooth, or to the pitch of the teeth of the sheave-wheel, will answer the purpose required. The wheel ss, from which

the twifting-sheaves ultimately receive their motion, is not necessarily concave, or fixed in this position. It may be placed at the foot of the shaft; and the axis containing the endless screw o, may be horizontal, or in any other position. The twisting-sheaves may also, if necessary, be each of them driven by a separate screw; or one may drive the other, by a cog-wheel on each: they likewise are not confined, either as to the place on the shaft, or relative position to each other.

FF. The cable stage, supported on rollers, and cut through, to shew the tiers and sakes of the cable.

G. The cable, paffing out of the fide of the cable-fhaft, and over the coiling-wheel p, which, by means of the iron fhank t, is drawn in and out, fo as to lay on the fakes or different turns of the cable, one within or without the other, as it winds in or out, after finishing every tier or layer of rope. In this inftance, the utmost diameter of the cable stage is 16 feet, and the innermost part (of where it is proposed to coil) 8 feet: this, in a 16inch cable, will admit of nine fakes in a tier, and the mean length of each fake will be little above 6 fathoms, and of the whole tier about 56 fathoms; consequently the coiling-wheel p must move inwards or outwards four feet in the time (or in less time) that 56 fathoms of cable are laving; which, according to the standard of hard twisting

twifting already affumed, would be done in 336 revolutions of the cable-fhaft; that is, it would move one inch in feven revolutions. Moving inwards or outwards, in lefs time, will be attended with no further inconvenience than leaving a space between the fakes, and sooner completing a tier. As the length of the fake increases or decreases, the wheel p ought to be moved slower or faster inwards and outwards; but this would be attended with unnecessary complication of machinery, and therefore the medium motion may be sufficient, as it will only occasion the cable to incline a little inwards or outwards.

One mode, out of many, of giving this motion, is as follows: the shank t may be formed as a screw, for the necessary length, and have the space of a revolution of thread to be half an inch, and pass through a nut u, containing a female fcrew; then, in the instance of a 16-inch cable, the nut would have to make two revolutions, in a period not exceeding feven turns of the cablefhaft, but fay in fix turns; then, let there be two fmall wheels v v, Fig. 6, each with an endless fcrew w, or w upon its axis, and the wheels of the same diameter as the wheel y, on the foot of the axis of the wheel r, Fig. 3, and connected with the fame wheel y, Fig. 6, confequently performing fimilar revolutions. Thefe wheels vv must be on a frame, capable of moving

a short space in the curved dotted line w x, whose centre is in the axis of the wheel y, therefore never lofing their connection with it; and, accordingly as the shank t is to move inwards or outwards, the endless screw w, or the endless forew x, is to be acting on the nut u, which nut is to be supplied with different numbers of teeth, and fineness of pitch, capable of being easily affixed and taken off: as also must the axis of the wheels v v be supplied with endless screws of correfpondent space of thread. The nut wheel u, in the inftance in question, having to make one revolution in three turns, and the wheel r making 36 revolutions in that time, it follows, that the nutwheel should have 36 teeth. In a cable of half the fize, to coil it close, it should have twice the number of teeth; but, as no material inconvenience will arise from its loose coiling, the same wheels and screws may be dispensed with. As to the change of motion, I propose to give it in the following, or any other manner, viz. that when the coiling-wheel p has proceeded to its extremities, either inwards or outwards, its axis q shall then fet in motion what in fteam-engines is usually called a spanner; which, being connected with the frame fupporting the wheels v v, shall put the fcrew on the axis of one wheel out of geer with the nut u, and throw the her in, so as to give the contrary motion. Alfo all, or part, of this machinery Vol. IX.

machinery may be difpenfed with, because, in large cables, the stage will move so slowly that men may stand in it to coil them away, as in a ship's cable-stage.

By means of the rollers, or by wheels affixed to the coiling-ftage, it will move fufficiently eafy. Some refiftance to motion is necessary, that it

may recede as the rope advances.

If 60 fathoms of 16-inch cable be made in one hour, the rope-shaft, according to the above premises, need only make 6 revolutions in a minute, and, if not hard twisted, only 5 turns, or as low as $4\frac{1}{2}$.

Smaller ropes, to be laid in the fame time, must make a number of revolutions inversely as their fizes.

In Fig. 1, a method of giving motion to the strand-shafts and rope-shaft is shewn, adapted to the contrary and different motions of shroud and cable-laid ropes. In this instance, A, represents (in section) a shaft that may give motion to as many sets of machinery as requisite. 1, is a cogged face-wheel on the lying shaft, working into the spur-wheel 2; which, by a small movement, must be capable of being disengaged from the wheel 1, and be put into geer with another wheel, (on the same lying-shaft A,) similar to the wheel 1, and with cogs opposite to it, so as to move the spur-wheel 2 the contrary way round.

The double bevel-wheel 3, is on the fame axis with 2, and works on one face into the wheel 4, on the upright shaft B; and, on the other face, the opposite side of the wheel works into the bevel-wheel 5, on the shaft C: therefore the shafts B and C move the same way round.

The wheels 4 and 6, being of equal diameters, and both faces of the wheel 3 being alike, it follows, that the shafts B and C must move with an equal number of revolutions. As the wheel 6, on the shaft C, works into the wheel g, at the foot of each strand-shaft, and is of the same diameter with them; and as the wheel 7, on the shaft B, works into the wheel 8, on the rope-shaft, and is but $\frac{1}{3}$ of its diameter; it follows, that their revolutions will bear the same proportion with each other, as that which has been mentioned to be nearly the medium in shroud-laid ropes. Any other proportion, at the option of the manufacturer, may be obtained as easily.

To adapt the same machinery for making a cable-laid rope, the shafts, in the first instance, must all move the contrary way. This is effected by disengaging the wheel 2 from the wheel 1, and putting it into geer with the opposite facewheel, already described. The remaining part is, to make the revolutions of the strand-shaft and rope-shaft equal. This will be obtained by lowering the wheel 7 so much, down the shaft B, as

to disengage it from the wheel-8, and bring the wheel 9 into geer with 10; which, being of equal diameters, and having the same proportions to each other as the wheel 6 has to those on the foot of each strand-shaft, will consequently give equal revolutions to the strand-shafts and rope-shaft; which, combined with the contrary motion to what they had, is all that is requisite to form cable-laid ropes with the same machinery.

In Fig. 3, a cable motion only is shewn; and the spur-wheels of the shafts B and C are only half the diameter of the wheels of the strand-shafts and rope-shaft that they work into; and they, of course, move with revolutions equal to each other, as in the preceding instance.

If found necessary to give different proportionate revolutions to the strand and rope shafts, in making shroud-laid ropes of a greater or less number of yarns, the disparity will be trivial; and the effect desired may easily be produced, by having the wheel 7 to take off, in two or more parts, and substituting in its place another wheel, of greater or less diameter, which will be brought into geer with the wheel 8, by shifting the foot of the shaft B a little inwards or outwards.

Fig. 6, is a horizontal plan, on an enlarged scale, of the coiling-wheel, with its supporting rails, and machinery for reverse of motion, which are

shewn

shewn in elevation in Fig. 3. Figs. 7 and 8, are alfo on an enlarged scale. The former of their shews the above apparatus in elevation, fimilar to .Fig. 3, and the latter is likewife in elevation, but transversely to Figs. 3 and 7. The following letters of reference are common to all those figures, fo far as they are to be found in any of them; viz. E, the rope-shaft, through which passes t, the shank of the coiling-wheel p. z, z, are the rails on which the coiling-wheel is supported, by the trucks or rollers a 1, a 1. a 2, is a forked bar of iron, fastened at one end by a pin to the bar a 3, which moves on a centre at a 4, and is charged with a fufficient weight, at its head, to force the endless screw w into geer with the nut u, when affuming its present position; or to force the forew x into geer with u, when acquiring the pofition of the dotted line, as at a 5. a 6, is an upright bar, with a pin through it, to support the bar a 2 at fuch height as that it will not rest against q, the axis of the coiling-wheel. I shall here observe, that the lower limb of the bar a 2 may be difpenfed with. a 7 and a 8, are moveable flides, to be fixed fo far short of the innermost and outermost range of the coiling-wheel as nearly the length of the opening in the bar a o. which passes over b 1, a shank connected with the moveable frame of the wheels v. v.

According

According to the position of the bar a 3, the cooling-wheel must be moving outwards: when q arrives at a 7, it will carry forward with it the bar a 2, until it brings the foot of the bar a 3 past the perpendicular under the centre a 4, and the opposite end of the groove on a 9 near to the shank b 1: at which time, the weight on the head of a 3, preponderating the contrary way to its former position, begins to assume that of the dotted line a 5, and consequently carries along with it the shank b 1; which, disengaging the endless screw w, and putting the endless screw w into geer with the nut u, gives the contrary motion required.

EXPLANATION OF Fig. 9. (See Plate IV.)

The principle of coiling the rope here is nearly the fame as in the coiling-stage; the reel making so many revolutions less than the rope-shaft as there are coils of the rope upon it; the difference chiefly consists in this mode admitting the shafts to be horizontal, if that position should be deemed eligible. To enable the rope to be coiled in a sufficiently small space, it is necessary, that either the pulley-wheel a should move inwards and outwards, as in the plan for the coiling-stage, or that the reel (or wheel on which the rope is to be wound) should change its relative position with

the wheel a, by shifting its place on the axis of the rope-shaft; the latter of which may be done various ways, and, amongst others, by the fol-· lowing method; viz. the outer rim of the wheel b.b should move through the notch of a moveable block c, that travels backwards and forwards, for a space nearly equal to the length of the axis of the reel. This block a should have such a compressure upon the rim of the wheel b b, as to be equal to the pulling it round, as the twifting fheaves give out the rope; and it may be moved backwards and forwards by a crank d; the crank being rather fhorter than half the length of the axis of the coiling-reel, because of its flower motion towards each extreme. The wheel e, upon the same arbor with the crank, should move with different velocities, according to the thickness of the rope to be coiled up; which (as it must receive its flow motion by the intervention of other wheels, to which a belt may be applied in the rapid part of the movement) may be done by having drum-wheels of different diameters; and confequently any velocity may be given, proportionate to the fize of the rope. This description, even without the aid of the previous examples I have given, is fufficiently plain to any millwright, or person conversant in mechanics, to whom alone a description of mechanical subjects can be made clearly obvious, even with great prolixity.

EXPLANATION OF Fig. 13. (See Plate IV.)

B, is the transverse section of a shaft, similar to B in Fig. 1. 66, is a spur-wheel at the upper end of it, to perform the same operation as the wheel 6, on the shaft C, in Figs. 1 and 2. This wheel 66 is connected with as many wheels g, g, as may be convenient to place round it; each of them turning a strand-shaft D, the same as in Figs. 1, 3, and 11.

In the present instance, the wheel 6 6 is of 6 feet 6 inches diameter, and the wheels g, g, &c. of 2 feet, making 13 revolutions for four of the shaft B; and there are 12 strand-shafts, confequently, applicable to three lower shafts, for four strand-ropes, or four shafts for three strand-ropes: this plan is drawn to correspond with the latter. E, represents one of the four rope-shafts, and 8 the wheel upon it, fimilar to 8, in Fig. 1. 77, is a correspondent wheel, on the lower part of the fhaft B, and gives motion to all the rope-shafts. The diameter of 7 7 is 3 feet 9 1-inches, and that of the wheels 8 8 is 3 feet 6 inches, viz. in the proportion of 13 to 12; confequently, as the wheels 6 6 and g g are as 13 to 4, the ftrandshafts will make three revolutions to one of the rope-shaft. In the same manner as described, any number of machines may be placed round

the fame shaft or arbor, and any proportionate velocity given to the strand and rope shafts.

Also, if found necessary (which can only be in ropes of a small number of threads) to twift the yarns, during the process of making a strand, it may be done by a number of fmall shafts, placed as D, D, round the whole, or round a portion of the circle, and giving motion to them by a belt. A reel with a fingle yarn may be placed, as in Figs. 10 and 11, on as many of them as there are yarns in the strand; and all these, concentring about a top or laying-block, may join at a proper distance in one shaft, as at B, similar to the ropeshaft E, Fig. 1. This shaft also, like the small fhafts with fingle threads, may receive its motion from a belt, and move with the fame number of revolutions; its use (with yarns properly twifted) being only to prevent the twift from being taken out of the yarns, by the contrary twifting of the rope; which may equally be effected by giving the varns for small ropes a more than ordinary twift.

Description of the Process of Tarring and Warping.

In the methods I have described, of making ropes, or strands of ropes, where each yarn, or number of yarns, has to take its proper place, it

Vol. IX. G is

is necessary that every yarn, or small number of yarns, should be separately wound up, and the mode of performing this becomes an effential and constituent part of my method or methods of making ropes.

The mode that I have invented is applicable to. and a part of, my method of making tarred ropes. The principle of it confifts in winding up feparately, during the process of tarring, each individual yarn, or fmall number of yarns, as may be previously determined. In the common method of tarring, which is frequently done to the extent of three or four hundred yarns at one time, they are, as they come from the tar-kettle, paffed in the mass through an opening, where they receive fuch pressure as to force back the superfluous quantity of tar; and they are drawn forward by the mass of yarns being passed any requifite number of turns round an axis, which is moved by a horse, or by any other means; and the whole is progressively coiled up. In place of this, my method is, to draw forward, and wind up, any determinate number of yarns, by their ends being fastened to their respective reels, one or more to each; and, as it is necessary to keep the yarns from entangling, in their paffage from the tar-kettle, or other veisel, to their reels, I occasionally prefs them feparately, in fuch a manner as that each reel shall draw forward its own yarn or yarns,

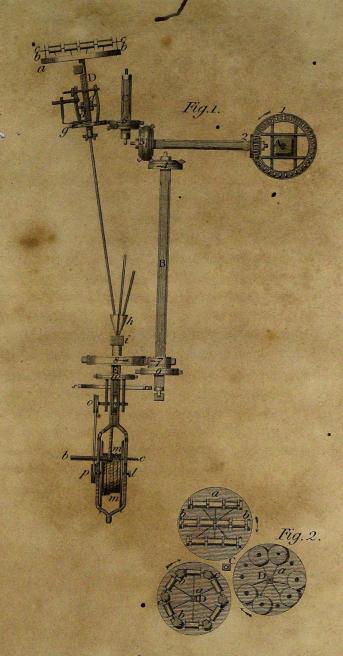

yarns, independently of the rest, similar to what I have defcribed in the paffage of the yarns through the firand-fhaft; which may be done by one general preffure, the yarns being divided in layers, by the intervention of coarfe woollen cloth, felt, or any other elastic or pliable substance, and in the transverse direction to those layers: they may be farther separated by the insertion or intervention of metal or wooden pins, or other divisions, which must have correspondent openings or grooves, either in the press-block, or place pressed against. It is only necessary farther to observe, that not any of the reels on which the white yarns are wound, and from which they unwind as they pass into the tar-kettle, should pass its yarns to two or more reels, as inconveniencies would thereby arise in regulating their manner of winding up; confequently, the white yarn should be on as many feparate reels as the tarred yarn is proposed to pass on to at the same time. By these means, during the process of tarring, any requifite length of tarred yarn may be wound up, and cut off, and other reels may be substituted for the continuation of the process, for the refidue of the yarn. In the passage of the yarns through the tar, it will be eligible to keep them feparate, by passing them through distinct openings in the piece of metal ufually called by ropers a foot; one or more of which is fometimes used

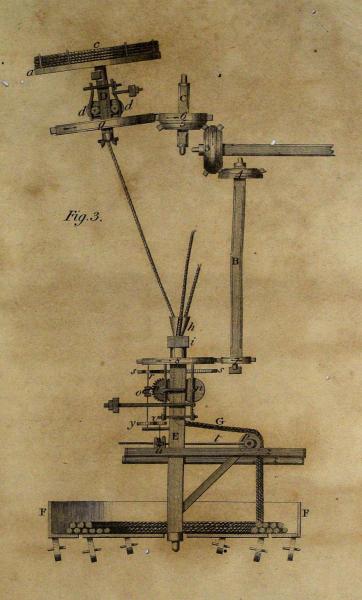

to keep the yarn under the furface of the tar, in its passage through the kettle. According to this method, much of the trouble requisite in warping, or laying out the desired length and number of yarns for making a strand of a rope, will be saved.

Observations on the Scale of the Plans, &c.

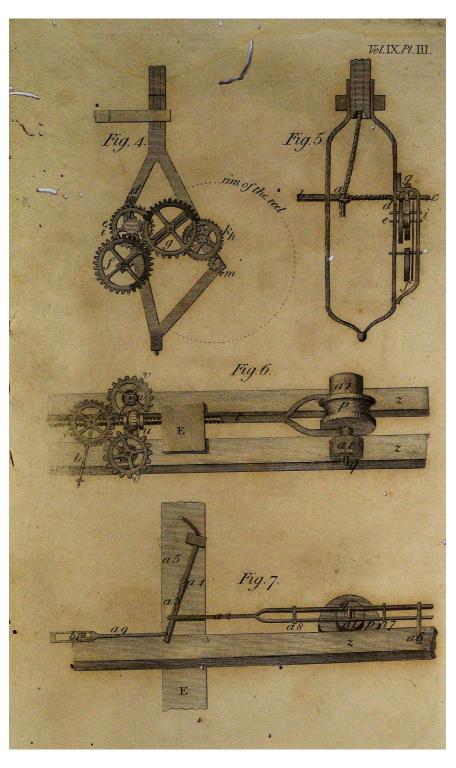

The figures themselves are not meant to give any decidedly fixed, or relative proportions of the different parts of each machine; but, as they may be carried into execution on the dimensions that are delineated, I shall observe, that all the figures, excepting 4, 5, 6, 7, and 8, are drawn on a scale of $\frac{1}{6}$ of an inch to a foot; and the figures last mentioned on a scale of half an inch to a foot.

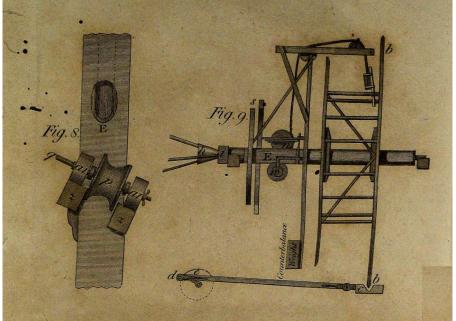

It must likewise be noticed, that the teeth or cogs on the wheels are, in some parts, omitted; the description and figures combined being deemed sufficiently explanatory without them. In witness thereof, &c.

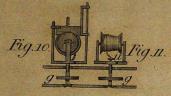

Bafire So.

II.. Specification of the Patent granted to Mr. John Howell, of the Parish of Oswestry, in the County of Salop, Coal-master; for an improved Engine or Machine for the Purpose of boring or hollowing wooden Water-Pipes or Aqueducts, in a much more expeditious Manner than hitherto practised, and whereby a considerable Saving will b made in the Article of Timber.

Dated May 31, 1796.

To all to whom these presents shall come, &c. Now know xe, that in compliance with the said proviso, I the said John Howell do hereby declare, that my said invention is described in manner following; that is to say, instead of the common method of boring by augres, or instruments of any other description which persorate the wood by cutting out the inner part of the substance in chips or shavings, a hollow tube or cylinder, made of thin plates of iron, or other metal, about one inch less in diameter than the hole to be bored, is to be made use of. To one end of this tube or cylinder is to be fixed a flanch or ring.

ring, of from one quarter of an inch to five eighths of an inch in breadth; and one part of the circumference of this flanch or ring is to be divided or separated, so that, if it be made of steel, an edge or cutter may be formed thereby: or, for the more convenient use of it, a cutter of fteel, or other metal, may be screwed, or otherwife connected with the tube and the flanch or ring. The operation of this inftrument is, that it will bore out of a piece of wood, whilst forming it into a pipe, a folid piece of wood, capable of being converted into a pipe or pipes of less dimensions: and that it will do this with the aid of less power, and at less expence, and with less waste of wood, than by means of the boring inftruments now in use. In witness whereof, &c.

III. Specification of the Patent granted to Mr. William Bell, of Walfall, in the County of Stafford, Engineer; for a Method of making Needles, Bodkins, Fish-Hooks, Knitting-Pins, Netting-Needles, and Sail-Needles.

Dated Sept. 8, 1795.

TO all to whom these presents shall come, &c. Now KNOW YE, that in compliance with the faid provifo, I the faid William Bell do hereby declare, that the method by which I make needles, bodkins, fish-hooks, knitting pins, netting-needles, and fail-needles, is by cafting them with fteel or common fufible iron, called pig or cast iron, into moulds or flasks made with fine fand. Or otherwife I make flocks or moulds of iron or fleel, cr any other composition capable of being made into moulds; on which ftocks or moulds I fink, engrave, or ftamp, impressions of the faid articles. Into those I pour my melted iron or steel, (I prefer, for my purpose, fand-casting,) and prepare my iron or fteel as follows. I melt it in a pot or crucible, in fmall quantities, about the weight of twelve

twelve pounds, (and upwards to twenty pounds,) the more conveniently to divest it of its heterogeneous particles, and to purify it from its earthy or fulphureous qualities. When the iron has attained a proper heat, I take charcoal dust, mixedwith lime, or common falt, which I throw into the pot of melted iron; and, by frequently stirring it with an iron rod, I bring to the furface of the iron a scoria, which I frequently skim off, and thus bring my iron into a refined flate. I then pour it into the mould before described. The articles being thus formed, are capable of being foftened, hardened, or tempered, in the usual way by which needles, bodkins, fish-hooks, knitting-pins, netting-needles, and fail-needles, have heretofore been manufactured; therefore, the principal merit of my invention is in cafting them, instead of making them in the usual way. In witness whereof, &c.

IV. Account of an Experiment to afcertain the Quantity of Butter and Cheefe producible from a given Quantity of Milk. By Mr. JOSEPH WIMPEY, of North-Bockbampton.

From the Letters and Papers of the Bath and West-of-England Society for the Encouragement of Agriculture, &c.

As experiments to determine the comparative value of butter and cheefe have been thought of fome importance, I take the liberty of prefenting one to the fociety: it is on a fmall fcale, but made with great care and exactness.

One hundred and five gallons and a half of milk were properly disposed in pans for skimming off the cream. It produced thirty-fix pounds of butter, and fixty pounds of skimmed cheese. The low average of good butter, in this neighbourhood, is 8½d. per pound: and the skimmed cheese was fold for 2d. per pound. I am informed that this fort of cheese, three or at most four years fince,

Vol. IX. H fold

fold only for a penny farthing, or at most three halfpence, per pound.

36lb. of butter, at $8\frac{1}{2}d$. 60lb. of skimmed cheese,	- at 2d.	I	s. 5 10	6
Total,		1	15	6

Of a like quantity of milk, namely, one hundred and five gallons and a half, were made one hundred and fix pounds of raw-milk cheefe, and fix pounds of whey-butter. The cheefe, at two months old, was worth at least $3\frac{1}{2}d$. per pound, and the whey-butter fold at 7d. per pound.

	£.	5.	d.
106lb. of raw-milk cheefe, at 3 ¹ / ₂ d.			
6lb. of whey-butter, at 7d.	0	3	6
Total,	I	14	-

From this experiment it appears, that when the butter and cheefe, of each fort above mentioned, tioned, will fell for the above prices, a small advantage lies on the side of butter and skimmed-cheese. It amounts to 13d. only in £.1. 15s. 6d. which is about three per cent.

Butter from half new milk and half whey, would be of a middle quality between the other two, and the cost-price of course must be so too, and so must cheese from half-skimmed milk; each of these may be varied in goodness, according to the proportion of milk and whey, and of the milk skimmed and unskimmed; so that the price of the latter may be varied from 20s. to 30s. per hundred. But the advantage of following either course depends upon local circumstances, as was observed before; and the dairyman, to acquire the greatest profit, must regulate his mode of practice accordingly.

V. Account of an Improvement made in the Mercurial-Level invented by ALEXANDER KEITH, Efquire, F. R. S. and A. S. Edinb. * By the Inventor.

From the Transactions of the ROYAL SOCIETY of EDINBURGH.

THIS improvement confifts in a contrivance for avoiding the trouble of pouring the mercury out and into the level, every time it is used. Besides the canal of communication at the bottom, between the two upright columns of mercury, on which the floats swim, (see Vol. III. Plate XIX.) there is, in the new manner of constructing the instrument, another canal, parallel to the former, cut in the upper part of the wood, which allows the air to circulate freely, according as the mercury below rises or falls. The

whole

^{*} A description and figure of this level is given in our third volume, page 338.

whole is made perfectly close, so that no more air can get admittance.

The inftrument may be carried about, when conftructed in this manner, with the mercury remaining in it; and though, by agitation, that fluid calcines, and is converted into a grey powder, this only happens when it has free access to vital air; but, as all such access is here prevented, the mercury will not lose its metallic lustre.

The level, in this form of it, as it requires no previous adjustment, is very commodious; and, when much accuracy is not required, may be used with advantage.

VI. Conjectures relative to the Cause of the Increase of Weight acquired by some heated Bodies, during ecoling. By THOMAS HENRY, Junior.

From the Memoirs of the Literary and Philosophical Society of Manchester.

MANY experiments have been made, by different perfons, with a view to determine, whether the addition of actual heat to bodies does increase their weight. M. Buffon has afferted, that a ball of iron, weighing when cold 49 lb. 11 oz. increased in weight, when made of a white-heat, in the proportion of 19 ½ grains to every pound. But it is very probable, that in this experiment there was some fallacy, since we find it directly contradictory to the results of the experiments made by Dr. Roebuck *, and of those made by Mr. Whitehurst . The first of these two gen-

^{*} Phil. Tranf. Vol. LXVI, page 500.

⁺ Ibid. page 575.

tlemen found, that a cylinder of wrought-iron, heated to a welding heat, at which time it weighed, in a very accurate balance, forty-five pounds, gradually acquired, as it cooled, an increase of weight; fo that, at the end of twenty-two hours. it weighed fix penny-weights feventeen grains more than it did when first committed to the balance. This phænomenon, which by fome has been adduced to prove that heat is the principle of levity in bodies, Mr. Whitehurst has endeavoured to explain, by supposing that, the air above the scale being rarefied by the heated iron, the cold air below rufhed up, and, ftriking against the bottom of the scale, not only prevented its defcent, but even buoyed it up. Something may, perhaps, be attributed to this cause; but be nearly as much rarefied as that above? And, is it not probable, that the supposed force of this teracted, by the greater tendency a body has to descend in a rarefied, than in a dense medium? Is it not probable, likewife, that the end of the beam, to which the heated iron was appended, would, by the same heat which rarefied the air. be more expanded, and lengthened, owing to its nearer approximation to the fource from which the heat flowed, than the more distant end of the

beam? I would likewife observe, that in the experiment of M. Buffon, above quoted, and in one made by Dr Roebuck, on a smaller scale, the mass, owing perhaps to the joint action of the above causes, weighed more when hot than when cold.

Having thus endeavoured to fhew the infufficiency of the explanation given by Mr. Whitehurst, I will venture, with the greatest diffidence, to propose the following query. May not the increase of weight acquired by heated iron and copper, during cooling, be afcribed to the calcination and confequent absorption of air, continuing to proceed after the removal of the mass of metal from the fire, the absorption of air in particular, in the first stages of cooling, perhaps with increased rapidity? In support of this conjecture, the following facts may be adduced: First, that fome metals, particularly copper *, are found to calcine more rapidly in a moderate degree of heat, than in one more intense. Secondly, that the calces of some metals, as that of lead, have been observed to increase in weight by long exposure to the air; and that they then afford, by proper treatment, more air than could have been obtained from them, previous to fuch

^{*} Macquer's Inft. of Chemistry, Vol. I. exposure.

exposure. Thirdly, we shall find, by examining Dr. Roebuck's account of his experiments, that the weight continued to increase, long after the cause assigned by Mr. Whitehurst must have ceased to act. The cylinder, which was repeatedly weighed at intervals, when it had been in the scale fix hours, and had then lost so much of its heat as to be only blood-warm, was found to be acquiring weight, in the proportion of feven grains in the space of an hour *. But, when weighed the day following, at the expiration of twenty-four hours after the commencement of the experiment, it had acquired a ftill farther addition, of two penny-weights and feventeen grains, which, according to the above progression, it would have required at least nine hours and a half, nay most probably even a longer time, to accomplish. If to these nine hours and a half we add the preceding fix, we obtain fifteen hours and a half; a period, long before the expiration of which, the mass of iron must have taken the temperature of the furrounding bodies, fince the

Vol. IX. I first

^{*} During the two first hours of its exposure in the scale, the increase of weight had proceeded with much more rapidity: in the third hour, it proceeded less quickly, and continued to diminish gradually in celerity, to the expiration of the fixth.

first fix of these were sufficient to reduce it from the welding point down to blood-hear.

I shall conclude by observing, that metals, which are the only bodies hitherto employed to determine this point, are certainly, from the changes they undergo by the action of heat, very ill-adapted to the purpose; and that, to arrive at any degree of certainty, it will perhaps be necessary to weigh the body in vacuo, or at least in a vessel so confined as that any current of air through it shall be prevented; also, that the beam of the scales shall be formed of materials less liable to expansion by heat, than metals in general are.

VII. Account of a Method of fixing Mercury. By
Dominick Vandelli, Professor of Natural
History and Chemistry, in the University of
Coimbra.

From the Memoirs of the Royal Academy of Sciences of Lisbon.

By caufing the vapour of mercury to pass through a tube of iron, full of nails, and redhot, I obtained (attached to the nails) globules of mercury, which had the colour of filver, and the confishence of tin.

We think it necessary to inform our readers, that the whole of the original paper is here translated, lest they should suppose it impossible that so curious a discovery as a method of fixing mercury (otherwise than by cold) should be announced, by a professor of chemistry, in so very crude and unsatisfactory a manner. No mention is made of any means used to ascertain the purity of the mercury made use of; nor is it said that any experiments were afterwards made upon the globules of metal, to determine whether they were really mercury or not. From these circumstances, and indeed from the general tenour of the experiment, we think our chemical readers will be strongly inclined to suspect, that the metallic globules here spoken of consisted merely of lead, or tin, with which the mercury was adulterated.

VIII.

VIII. On the Composition of Writing-Ink. By M. RIBAUCOURT, Member of the Academy of Sciences of Rouen, &c.

FROM THE ANNALES DE CHIMIE.

HERE are few chemical preparations, perhaps none, of which the benefit in civil life is fo great, or of which the use is so widely extended, as that of common writing ink; confequently, there is no preparation the quality of which it is more necessary to enquire into, yet there is perhaps none which has been more neglected by chemists. Before Lewis, no author appears to have particularly applied himself to enquire into the theory of this composition, and to endeavour to bring it to perfection. All that is to be found in the works of a fmall number of other writers confifts merely in some formulæ for making ink, which, being composed without any attention to chemical principles, are more or less desective; fo that it may be truly faid, that, until the time of Lewis, the preparation of this liquor, the properties of which it is fo effential to attend to, was left entirely to chance.

It is indeed true, that fome good kinds of ink have been discovered by chance; but those who discovered them have kept their composition a secret, so that the public were obliged either to purchase those inks of the inventors, or to make use of such as were inserior in quality, and more or less perishable. As the theory of this liquor was very little known, there has been, till now, no basis upon which any principles for preparing it in a more fixed and certain manner could be established.

The small number of authors who have, in a curfory manner, said any thing respecting ink, have confounded it with the black dye for cloths, &c. because the basis of one was similar to that of the other. But I must observe, with Lewis, that although the ingredients which enter into the composition of ink are in part the same as those of the black dye, there is however some difference in the proportions, &c. Many of these mixtures, which are too perishable, when supersicially applied upon paper, are sufficiently permanent, when introduced into wool; and other mixtures, which produce a good black upon paper, give only a brown colour when employed in dying.

I may add to this observation, that not only the proportions, &c. vary, but likewise, that though the bases are the same, the other ingredients are not so; for it is possible, as some authors have observed. observed, (particularly M. Berthollet,) to dye black, by substituting oak-bark, sumach, and many other vegetable aftringents, in the place of galls. But these substances, although they produce a fine black colour when used in dying, cannot be used for making ink; which liquor cannot be made to have a beautiful and durable colour, without the affistance of galls. There is, consequently, a great difference between the liquor used for dying black and ink.

On the Ingredients commonly used in the Composition of Ink.

Galls and fulphate of iron (green vitriol) always form the basis of ink: gum-arabick also generally enters the composition.

Some authors add fugarcandy thereto; others reject it.

Lewis adds logwood to the composition.

Some persons add sulphate of copper (blue vitriol) to it; others add verdegris.

Geoffroy makes use of alum.

Lastly, according to Lewis's account, many persons substitute sulphate of copper, or of zinc, (white vitriol,) in place of the sulphate of iron.

With

With respect to the liquid made use of, distilled water, rain water, or common water, are, according to Lewis, equally good; some persons, however, make use of beer, others of white wine, and others of vinegar.

It appears, therefore, that there is a great difference between authors, respecting the ingredients which ought to enter into the composition of ink, and that they agree only in making use of galls; that being the only ingredient which enters universally into every formula. This difference can only proceed from the want of a common theory, respecting the nature and properties of these ingredients, and of their manner of acting upon each other, particularly of the sulphate of iron and galls.

I shall not treat of the natural history of the substances which enter into the composition of ink; nor shall I give the chemical analysis of any of them, (except galls,) both one and the other being so well known, that I could only repeat what other authors have said. I shall therefore confine my observations to the examination of those substances which contribute, either to the blackness of this liquor, or to its consistence, or to its permanence; qualities which, when united, constitute its perfection.

Analysis of Galls.

All the analytical experiments I am now about to describe, and likewise what relates to the reciprocal action of galls and sulphate of iron, are extracted from a paper I wrote in the year 1782; which paper I sent to the Academy of Sciences of Rouen, in 1791. I always operated upon Aleppo galls; that being the fort which ought always to be chosen, in preference to any other, if it be wished to obtain the best ink possible.

Galls, when distilled with water, at the mean temperature of boiling water, produced a liquor which gave a purple colour to a solution of sulphate of iron.

Eleven ounces of galls, put into a retort, placed in a reverberatory furnace, produced, first, an infipid phlegm, the first portions of which gave a purple colour to a folution of sulphate of iron; and afterwards a small quantity of phlegm, which was slightly acid. I did not weigh these two quantities of phlegm; they were followed by two ounces and three drachms of an acid empyreumatic spirit, mixed with oil.

A folution of potash, poured upon a strong decoction of three ounces of galls, precipitated from it nine drachms of a grey earth, which was soluble, with effervescence, in acids. The filtered liquor was rather turbid. A fmall quantity of a folution of potash, being again poured in, gave it a dark-green colour, and precipitated from it a small quantity of a brown matter. The filtered liquor was transparent, and had a fine green colour.

This last liquor was evaporated to dryness; its residuum, after being calcined in a crucible, furnished, by lixiviation and evaporation, some very white sulphate of potash.

These products, from the analysis of galls, shew that the principle which gives a black colour to iron is volatile, fince it rises in distillation, with the mean heat of boiling water.

We are also shewn thereby, that galls contain all the principles of which vegetables usually confist.

But what we particularly remark in this analyfis, and which ferves to explain the phænomena which galls prefent with fulphate of iron, is, that they give three drachms per ounce, of an earth fimilar to the abforbent earths; and that this earth is held in folution by an acid, or is in the frate of a falt with an earthy bafis, fince it is precipitated by the action of potash.

The fulphate of potash, which was surnished by the saturated decoction of galls, shews that galls contain a certain portion of sulphuric acid; and the green colour which that decoction retains, after the precipitation of the earth, shews that it contains iron.

I was furprifed that I obtained only a fmall quantity of fulphate of potash, very inferior to that of the acid indicated by the quantity of precipitated earth. I supposed that the salt, formed by the combination of the acid of the galls with potash, had been volatilized during the calcination. The experiments of Scheele upon this subject, which were not then known, have since justified my conjecture.

I do not know that any person before me, or indeed hitherto, has discovered the forementioned earthy salt in galls. This discovery has afforded me a clue to the theory of ink, in which we shall see that this salt acts the principal part.

I am also ignorant whether, until the publication of my experiments, it was known that sulphuric acid exists in galls.

The decoction of galls gave me, by evaporation, an extract, which had nothing particular in its appearance: I only observed, after having let it dry in the air, a great number of small saline crystals, in the form of needles, which I considered as the salt resulting from the union of the vegetable acid of the galls with potash. I tried in vain, by all known means, to obtain these crystals free from the extractive matter with which they were mixed.

Two ounces of galls gave me one ounce and three drachms of extract, of the usual confistence; which, after being thoroughly dried in the air, was found to be reduced to one ounce and twenty-four grains.

On the Action of Galls upon Sulphate of Iron.

I shall not repeat what has been already said, respecting the various changes of colour resulting from the union of these two substances, or respecting many other circumstances now generally known; nor shall I examine any of the systems which have been formed upon the subject; but shall only give an account of my own experiments, and deduce such consequences as appear to me naturally to result from them.

I poured a folution of one pound of fulphate of iron into a ftrong decoction of one pound of galls; I diluted the mixture with fuch a quantity of water, that the whole amounted to forty pounds; I then let it ftand undiffurbed.

After twenty-four hours, the liquor had acquired a very dark and blackish purple colour. I poured it off, and found at the bottom of the vessel a very coarse precipitate, which felt rough to the touch. I collected it upon a filter, and,

K 2 when

when dry, it was of a greyish blue colour, very compact, and brittle; its broken surface had a shining appearance. It weighed eleven ounces and a half.

I poured forty pounds of water into the liquor which I had decanted, and let it ftand for twenty-four hours.

At the expiration of that time, I found the colour of the liquor much lighter than at first; a fresh precipitation had taken place, which I separated as I had done the former. It appeared to be less heavy than the preceding, and was of a purplish blue colour, when dry. It was loose and friable between the singers, and appeared granulated and dull, when broken. It weighed four ounces and a quarter.

I again added forty pounds of water to the decanted liquor; and, after twenty-four hours, found that it had completely loft its colour. It did not appear that it contained iron, when tried with galls, or with Pruffian acid; nor that it contained earth, when tried with potash. It had deposited a small quantity of precipitated, which was light and loose, and of a bluish colour; less inclining to purple, and more inclining to black, than the preceding. It was more soft to the touch while yet wet, and more light and friable when dry. It weighed two ounces and a quarter.

I stould have been very much embarrassed to account for this successive precipitation, which took place every time I diluted the mixture of galls and fulphate of iron with water, if I had not had the example of what happens in the decomposition of alum by water, of which I have given an account to the Academy of Sciences, &c. of Rouen *. I therefore supposed, that a very large quantity of water would decompose metallic falts, in the fame manner as it decomposes alum; and it will be feen, that I afterwards verified this conjecture, with respect to sulphate of iron. But, first, I resolved to repeat my experiment, and to fee whether, by diluting the mixture with a fufficient quantity of water at once, I could not fucceed in entirely depriving the liquor of colour, and precipitate from it all the felenite, and all the oxide of iron, (charged with all the extractive colouring part of the galls,) by one operation, as I had before done by three.

For this purpose, I poured a solution of two ounces of sulphate of iron, into a strong decoc-

^{*} If, to a very clear and limpid folution of alum in water, a great quantity of fresh water be added, the mixture will grow turbid, and, if a sufficient quantity of water be employed, the alum will be completely decomposed, and all its earth will be precipitated. I found that ninety-sive parts of water were necessary to decompose, in this manner, one part of alum.

tion of two ounces of galls, and I diluted the mixture with fuch a proportion of water, as made the whole quantity of liquor amount to fixty pounds.

After the liquor had flood twenty-four hours, it had completely loft all colour, and gave no fign that it contained either oxide of iron, or felenite. I decanted it, and collected the precipitate upon a filter: it was of a blackish blue colour; and, after being dried, weighed two ounces and a quarter.

I must again repeat, that I consider the discovery of the phænomena which these two substances present, as a circumstance which serves to explain the action of galls upon sulphate of iron, and the theory of making ink, as well as that of dying black; and, although I do not mean to treat particularly on the latter subject, I cannot help making, as briefly as possible, the following observations upon it.

TO BE CONTINUED IN OUR NEXT.

IX. Lift of Patents for Inventions, &c.

(Continued from Vol. VIII, Page 432.)

Andrew Cederbarg, of St. John's-lane, Clerkenwell, in the county of Middlefex, Engine and Mathematical Inftrument maker; for a machine or inftrument for the purpose of glazing, polifing, and graining divers forts of leather, &c. Dated February 28, 1798.

WILLIAM CHAPMAN, of Newcastle-upon-Tyne, Gentleman; for a method of laying, twisting, or making ropes or cordage, of any number of yarns or strands, or any number of threads, tarred or untarred. Dated March 6, 1798.

HENRY GOOLDING, of Willesden, in the county of Middlesex, Yeoman; for a machine or engine for raising, removing, and carrying off earth, stones, or rubbish, so as greatly to facilitate, and render less laborious and expensive, the carrying on and executing the works of canals, &c. Dated March 10, 1798.

Benjamin Douglas Perkins, of Kingftreet, Covent Garden, in the county of Middlefex, M.A.; for a certain discovery made by his father, father, Elisha Perkins, of Plainfield, in Connecticut, in North America, Doctor of Physic; for a certain art of relieving and curing a variety of aches, pains, and diseases in the human body, by drawing over the parts affected, or those contiguous thereto, in certain directions, various pointed metals, and compounds of metals. Dated March 10, 1798.

WILLIAM BOLTON, Esquire, Captain in the Navy; for an improved capstan, to be used onboard ships, in capstan-houses, wharfs, &c. or wherever any great weight is to be raised, or refissance overcome. Dated March 10, 1798.

WILLIAM LESTER, of Yardley Hastings, in the county of Nottingham, Farmer; for a harrow upon a new construction. Dated March 10,

1798.

Joseph Haycraft, of Greenland Dock, Rotherithe, Block, Pump, and Gun-carriage maker; for a gun-carriage upon a new conftruction.

Dated March 23, 1798.

JAMES DOUGLAS, of the parish of Christ Church, in the county of Surrey, Machinist; for machinery for shearing and cropping woollen cloth, with shears, knives, or cutters, put in operation by various powers. Dated March 30, 1798.

REPERTORY

OF

ARTS AND MANUFACTURES.

NUMBER L.

Printed by JOHN NICHOLS, Red-Lion-Paffage, Fleet-Street, London.

X. Specification of the Patent granted to Mr. John Crooks, of Edinburgh, Chemist; for a new Method of making Soap, and Bleaching, by Means and Use of Mineral and Vegetable Alkalies.

WITH A PLATE.

Dated Dec. 12, 1797.

TO all to whom these presents shall come, &c. Now know xe, that in compliance with the said proviso, I the said John Crooks do hereby declare, that my said invention is described in manner following; that is to say, in making the soft soap, I use sish of any kind, whether in their original unmanusactured state, or in a state of refuse, after they have been used in other manusactures, such as, for example, after the oil has

Vol. IX.

been boiled or taken from them. When they are in their original state, I cut them across, in two or more places, according to their fize, and I fleep them in cold water, and ftir them about, till the blood is separated from them, so that, when the water is let off, it may carry off the bloody particles with it. The fish are then cut, bruised, or mashed, by means of any instrument by which other materials are cut, bruised, or mashed: the intention of this is, to accelerate the diffolution of the parts or substance of the fish, as hereafter mentioned; but, if they are not bruifed, the diffolution will take place, though it will be more flow. I then throw the fish, by means of iron or wooden ladles or shovels, into boiling vegetable leys, very caustic, of the common strength of foap-boilers original (not waste) leys; and which levs should have been as lately made as possible, or at least should be taken from a vessel in which they have been carefully closed up, and which should not be above four or five days old. The proportion of leys to fish, is as fix to ten parts, in weight. The fifh should be thrown into the levs gradually, according as what was before put in appears to be in a state of dissolution, or tending to it: they will diffolve flow or fast, in proportion to the strength of the leys. The fish and leys are then boiled together, on a flow fimmering fire, till the fifh is compleatly diffolved, which will be in from three to fix hours, in proportion

to the quantity of fish. The point of dissolution is known, when the liquor, being faturated, refuses to diffolve more; and, when it has arrived at that point, no more fish should be added. After the fish has been dissolved, it ought to be passed through a strainer. Tallow or oil, such as whale or foot or any coarse oil, or indeed any oil, or tallow, in the proportion of one part of weight in tallow or oil, and eight parts of fish, is then to be thrown into the boiling veffel, in which the heat should then be increased, and the whole continue to be boiled, at a boiling heat, till they are thoroughly united; but, about an hour before they are thoroughly incorporated, I throw into the veffel common turpentine; by which I do not mean oil of turpentine, but that fubstance known by the name of common turpentine, which is thicker than common treacle, (the intention of which is to prevent the fifthy fmell,) in the proportion of one part, in weight, of turpentine, to fixteen parts of the other materials. I add then palm oil, in the proportion of one part, in weight, of oil, to thirty-fix parts of the other materials: this is to improve the colour, when needful, otherwise it is unnecessary. The soap must then be spread about three inches thick, in a cool place, and kept there for a month, before used; during which time, it must be turned every two or three days, with shovels or hoes.

To make bard Soap. Fifh, when compleatly diffolved with caustic vegetable levs, in the manner above mentioned, are to have tallow thrown into them, in equal parts with the fish, and both to be boiled at a boiling-heat, until they are thoroughly united. The veffel is then to fland until cooled, in order to avoid the danger of its being cracked. And then, mineral leys, or mineral and vegetable leys together, both cauftic, added to rosin, are to be thrown into the vessel: the leys in the proportion of fix parts, in weight, to twenty parts of fish and tallow joined together: and the rofin in the proportion of five parts, in weight, to twenty parts of fish and tallow joined together. The whole is to be boiled; and, in about an hour after, the ftrongest waste falt levs. from the foap works, (not original leys,) are to be added, in the proportion of two parts, in weight, to twenty-five parts. The whole must then be boiled the ordinary time, as already mentioned, till the power of the leys is fpent; and then these powerless (commonly called waste) falt leys are to be pumped up, and fresh caustic mineral (not vegetable) leys are to be added, in the proportion of fix parts, in weight, to twentyfive parts, and the whole boiled till it become hard foap; which should then be melted in water, in the usual mode, and then put into frames, and cut into wedges, in the common way. If a hetter

better colour is wanted, palm oil, in the proportion above mentioned, may be added at the last bailing. In the different operations of dissolving and boiling, above mentioned, the liquor should be stirred about every ten or sisteen minutes, with an iron rake, or other instrument.

And, as fifth are often driven on shore, in such vast quantities that they are either not used at all, or used only for manure; to prevent this public waste, I put them into receivers, and, by pouring over them strong leys, sufficient to cover them, within two or three days after the fish are taken, or within such time as fish will commonly bear to be salted, I preserve them for being afterwards, at leisure, manufactured into saponaceous matter, or soap.

As to Bleaching, I take either foap-boilers waste leys, or bleachers waste leys, the last of which are got either from the boiling vessel, called the bucking vessel, or from the whitening vessel, called the gas-liquor vessel; and I put them into a cask, or other vessel of wood, or plate iron, which has two bottoms, separate from each other about an inch and a half. The upper one is perforated with a number of small holes: the under one has only one hole, of about an inch or more in diameter, according to the size of the vessel.

The interval between the two is filled with ftraw, mats, finall pebbles, or other fubftance pervi-

ons to water. The cask or vessel is then filled with the leys, the pure parts of which filtrate through the holes of the upper bottom, the substances between the two bottoms, and the hole in the under bottom; from which last they are received into a separate vessel, whilst the impurities remain behind.

From this receiver they are conducted, or pumped up, into a shallow pan or boiler, or more than one, of plate-iron, of whatever length and breadth is needed. The most commmodious method, for expediting much work, seems to be two boilers, placed by the side of each other, divided by a common wall, each ten seet long, seven seet broad, by sisteen inches deep; of which, six inches to be of plate-iron, and nine inches to be of a crib of wood; but slanting outwards, to contain the more leys, and prevent them from boiling over. Here the leys are boiled, and evaporated down to the thickness of treacle.

Adjoining to this boiling veffel, or these two boiling veffels, and connected with it or them by a pipe or funnel, or by two pipes or funnels, (if two evaporating veffels are needed,) each one foot long, and nine inches diameter, there is an oblong vaulted kiln or oven, about ten feet long, fix feet wide, and two feet and an half high, all built of brick; in which the leys, that have already been evaporated to the thickness of treacle,

are calcined. If there be only one evaporating veffel, the pipe or funnel, from the evaporating veffel into the calcining-furnace, will be in the middle of both. But if there be two evaporating veffels, separated by a mid-wall, then the two funnels will be placed near the common wall, and pointing obliquely into the calcining-furnace, fo that they may meet in one ftream in a point, in order to increase, as in a focus, the power of the heat. I prefer two evaporating vessels to one, because much longer time would be required, to evaporate a certain quantity of liquid leys into a substance as thick as treacle, than to calcine that fubstance into a black falt, as hereafter mentioned; whereas, if the calcining-kiln be fupplied only by one evaporating veffel, it will frequently ftop, and consequently cool, for want of work, However, manufacturers may vary their forms and dimensions at pleasure, because it will be easy to find out, by experience, the quantity of leys which can be evaporated, with most advantage to the manufacturer, in one veffel of a certain fize, and calcined in another veffel of a certain fize, and confequently to proceed upon the proper proportions in forming the works. The fame fire or fires, thus passing from the evaporating vessel or veffels into the calcining-kiln, will act as an air or reverberatory furnace, with the flame playing over the evaporated leys. Into this calciningfurnace,

furnace, there is to be thrown charcoal, but first broke into the fize of fmall mufquet-shot, whether made of coal, wood, peat, or other combustible matter; or peat, or fmallcoal, uncharred: charred faw-duft is best. The proportion is one fixth, as near as may be, (for a small variation will not be material,) of the weight of the evaporated leys: by this means, the combustible material will unite rielf to the acid contained in the alkali of the waste leys of the bleacher, and to the acid contained in the common falt, in the wafte leys of the foap-boiler, in the calcining-furnace, and thus form a fulphur with it, which will be diffipated in the operation of calcination, and part of it will become kepar fulphuris. There is also to be thrown into the calcining-furnace, new-burnt marble, as hot as can be drawn from the kiln, in the proportion of about one pound and a half of new-burnt marble, to eight pounds of evaporated leys; which new-burnt marble must be broke down or pounded to the fize of a common hazle nut, and the marble must be compleatly free of any irony, clayey, or fandy particles, or any other impurities. If marble is not to be got, lime may be used, but is not half so good. The difference between marble and lime is, that the first has no irony, clayey, fandy, or other impure particles in it, whereas lime has. The reason for using the calcined marble when quite hot from

from the kiln, is, that no time will be given for fixed air to get into it, and thereby weaken its power. But it is carefully to be attended to, that the evaporated leys, charcoal, or other above mentioned fuel, and calcined marble, must be thrown into the calcining-furnace altogether, at one time, and frequently stirred in the furnace, to make them unite, such as once every ten or sisteen minutes. There the whole is to be calcined into a black falt: it will take from eight to eighteen hours, to calcine it properly.

When this black falt is formed and cooled, it is to be thrown into a hogshead, or other wooden or iron plate veffel, having a double bottom, perforated with fmall holes in the upper, and with a large one in the under bottom, and the interval between the two stuffed with straw, or mats, or pebbles, as above described; and, upon the upper bottom the black falts are to be laid, to the amount or quantity of two thirds of the depth of the veffel, and the remaining third to be filled with water, which is to be allowed to fland upon them twelve hours: during the four first of these twelve hours, the black falts are to be ffirred about every ten or fifteen minutes; and, during all the time, the hole in the under bottom of the veffel is to be kept flut, that the water may not escape.

Vol. IX. M Laftly,

Laftly, this hole is opened, and then the pure folution of the black falt will pass through it into a separate vessel, while the impurities remain behind, in the interval between the two bottoms. The solution is to be evaporated in one of the evaporating vessels, where it will be converted into grey salts, fit for bleaching, dying, or rectifying.

In this state, the grey salts may, in bleaching, be used with greater advantage than any other alkaline salt, for two reasons; the first is, that its power will be increased, in proportion to the power of the calcined marble in solution that is in it. Secondly, as the acid of these leys is decomposed into a hepar sulpburis, and, by the calcination, mostly thrown off, they become more powerful solvents, and are more sit to take off the original vegetable oil of the cloth, or yarn, in bucking, than common vegetable alkalies (which contain no bepar sulpburis) can be.

Having thus obtained an improved material for boiling the cloth, or yarn, in order to take the vegetable oils from them in the bucking veffel, I next proceed to apply and make it effectual in whitening them in the bleaching veffel, by another improvement. For this purpose, I throw one pound of calcined marble, quite hot from the kiln, into any kind of veffel containing ten pounds of soft water; where, after being once stirred about, it must remain close covered up for seven hours,

or until the water has imbibed as much of the marble as it can, and then both are to be ftrained through a veffel with two fuch bottoms as above described. After which, I impregnate this solution with the common materials of what is commonly called gas or chemical liquor, till the folution be fully faturated; the effect of which is, that the marble folution will imbibe far more gas than common water can; for, as it is certain that the more alkali there is in water the more gas will be imbibed in it, fo the folution of calcined marble, operating as alkali, and being a substitute for it, will imbibe far more gas than fimple water by itself can; and the effect again of this complication, by the addition of the power contained in the calcined marble, and of the power obtained by the increased quantity of gas, will be, that this bleaching liquor will go farther in work, by admitting a greater quantity of water to be mixed with it in bleaching, and will moreover make that work better.

This is not all; I plunge the cloth, or yarn, from the bucking veffel, directly, and immediately, into the veffel in which the bleaching liquor, made as before mentioned, is contained, but without adding any new alkali to it; the effects of which are, first, that the yarn, or cloth, when taken from the bucking veffel, having imbibed and been drenched with my improved material, Ma

which has all the effect, and more than the effect, of fimple alkali, will fave the expence of new alkali being put into the whitening veffel. Secondly, the improved material, thus imbibed in the cloth, or yarn, will, in the fame manner as if it was common alkali, (for which it is a substitute), destroy any acid, and consequently prevent the cloth, or yarn, being hurt by any acid, which, in making the gas-liquor, may have got over from the retort which contained the gas materials, into the receiver which contained the folution of marble. But, thirdly, it will make perfectly unneceffary the circuitous mode of bleaching used in most parts of Europe, and in too many of Britain and Ireland, of taking the cloth, or yarn, from the bucking veffel, and fpreading it in the fields, to get the advantage of fun and air, (but by which they often expose them to the dangers of both,) and of boiling and re-boiling them, with a new charge of new alkali each time.

And, as fome persons may not like the trouble or risk of combining either grey salts or other alkaline salts with calcined marble, I calcine either the one or the other with hot new-burnt marble, and put them, in a dry state, into stone vessels closely corked, and sealed with rosin, to prevent fixed air from entering, and thereby weakening their causticity; so that these persons will have no trouble, but afterwards to dissolve them in wa-

ter, as above mentioned, and to add the gas to the folution in the common way.

And as, in great towns or populous manufacturing neighbourhoods, the carriage of a bleaching material, even in a liquid state, (which I call bleaching liquor,) composed of solution of marble and of gas, is of little consequence, in comparison of the risk, danger, and loss of making fuch liquor improperly, and of fpoiling goods with it, (which fometimes happens to a very great amount,) I make the bleaching material in a liquid ftate; which, composed of those two articles, well corked up, may be transported from place to place, and from time to time, during the space of five or fix days, with fafety; because the folution of marble in it, acting like alkali, and being a fubstitute for alkali, will prevent the gas from being diffipated by the agitation of the water: which would happen, if there was nothing else but water and gas united together.

To facilitate, and render the discovery of my inventions more compleat, a drawing of the necessary works is subjoined. (Plate V.) In witness whereof, &c.

Sir John Dalrymple, Bart. (who is concerned in the patent) having favoured us with the following account of his examination before a Committee of the House of Commons, we insert it, as a farther elucidation of the discovery contained in the foregoing specification.

Questions to Sir John Dalrymple, Bart. by a Committee of the House of Commons, on the Fisheries.

Mr. Ryder in the Chair.

Question. What are the discoveries or improvements which you have made in making soap from fish?

Answer. Chiefly two, made by John Crooks, or me. First, we make soap by means of fish, alkali, and tallow. Secondly, we make saponaceous matter from fish and alkali; which may be preserved for months, or a year, and then turned into soap, by adding tallow to it. I consider the last to be the most important of the two, because making soap from fish is confined to the season of fishing; that is, while the fish continue fresh, and to the number of hands to be sound to make soap immediately from them: whereas the saponaceous matter

matter is inftantly made, and by few hands, and will keep long, to be converted into foap at leifure, and can be carried from place to place, according as it shall be needed, to mix with tallow for foap-works.

Q. What kinds of fish do you use, and in what state?

A. We began with the offal of whales; that is, with the refuse of the flesh of the whale, after the oil has been boiled from it; for which refuse I paid 6s. per ton; and I pursued it through every fish I found in market, and found them all succeed more or less, but with no great variation, except so far as related to the difference between hard or soft soap made from the same fish. With regard to the state of the fish, I used the whale-offal when all the oil was taken from it; and white fish, either fresh, or verging to putridity.

2. Did you use only their oily parts, or what parts of the fish did you use?

A. Oil has been made from fish, and soft soap has been made from the oil of fish, for ages past; but the singularity of our idea was, to throw heads, tails, bones, guts, skin, and, in short, the whole of the fish, together; and I never found any difference between the oil taken off by itself, and this mass taken altogether, to make soap; by which we did, at one operation, what other people did at two.

2. What are your operations and materials, and particularly, what is the proportion of tallow to the fifth, to make hard foap, and what the pro-

portion, to make foft foap?

A. My operations are the very fame as in making common foaps; and the materials (except fo far as relates to fish) are the fame. The proportions to make hard foap, are one ton of fish to one ton of tallow; but, to make fost foap, are eight tons of fish to one ton of tallow. From which confumption of the expensive article of tallow in the one case, and the saving of it in the other, I conclude, that the national saving must lie in the use of soft foap, which is sitted for nine parts out of ten of mankind, as I shall afterwards explain.

Q. What will be the faving in the expence, on

the hard foap and foft foap?

A. It will be proportioned to the faving of tallow in the two cases, but I cannot say how much,

2. Can you give to the foft foap fuch a degree of confiftence as will make it divifible into parts,

like hard foap?

A. My original idea was, to make foft foap at a cheap rate, for the foldiers and feamen, who, of one fort or other, are 400,000 in number, and I faid fo to the Duke of York and Lord Spencer. I carried it to Captain Shank, of the navy, who faid it could not be used by them, because, being of a soft texture, it could not be divided Vol. IX.

among the men, as hard foap was, which was out into wedges, and therefore I dropt that thought; but having, at the end of three months, examined it by accident, I was furprifed to find, that, by the mere lapfe of time, the aqueous parts had been carried off, and that it was of a divisible confistence. One of my fervants told me he had some still harder; and, when I asked him how that had happened, he said he had made some for his own private use, into which he had put some rosin. From these two circumstances, I am apt to think, that soft soap from fish may be made of a firm and divisible consistence.

Q. Will the fish-foap pay the bottoms of ships, and ferve in launching them?

A. I shewed this foft foap to Captain Shank, who said that it would.

2. Will the foft foap ferve in the manufacture of woollen?

A. I am told by foap-makers and manufacturers that it will. One of the last is now using it near London, from the second or third parcel that I ever made, with my servants, who had never made a pound before.

2. Will the foap ferve for washing?

A. A number of fervant maids, ferjeants' and feamen's wives, tried the foap, and never complained, except once or twice, when too much alkali put into it fmarted their hands.

2. Does it serve for shaving?

A. I have fhaved with the hard or foft foap indifcriminately: many of my friends have fhaved with the hard foap. The Duke of Portland and Lord Spencer made no complaint.

2. What are the trials you have made?

A. Mr. Bonney, an eminent foap-maker at Liverpool, made it first with offal of whales, next with white fish, and lastly with whale-blubber. I made it in Scotland and London with every sea fish that I could find. The Board of Trade here sent directions to the Board of Fisheries in Scotland, to make trial on a large scale, and report. They made half a ton of hard soap from herrings, and are now making another half ton from dog-fish, and are soon to make soft soap, and to report.

Q. Have you letters, or information, to make you believe that in the British seas there are fish enough, and at Newfoundland refuse of fish enough, to supply saponaceous matter, to be afterwards turned into soap in Britain, by joining with it portions of tallow, so as to serve the mar-

kets of Britain, and perhaps of Europe?

A. I have various letters to that purpose. I produce a copy of one of them, from a foap-boiler **

^{*} The letter here referred to (which is from Mr. Jameson, soap-boiler, of Leith) says, "the immense fishing now in the Firth, should it continue every season, will furnish an "ample source of materials for all the soap-makers in Britain."

who pays, or paid, (I forget which,) one fixth of the foap tax of Scotland. Mr. Jeffery, member for Pool, told me he could fend, from Newfoundland, as much faponaceous matter, from the refuse of cured fish, and fish driven on shore, as would serve all England, provided he could get alkali in Newfoundland.

Q. What do you imagine is the amount of the foap made in Britain?

A. 1,500,000 l. a year; which I calculate by comparing the produce of the tax with the value of the foap made. The tax upon hard foap is 2½d. per pound: the value is about 7 d. per pound. The tax yields 500,000 l. a year; therefore the value of the foap must be 1,510,000 l. I do not indeed take into my calculation the smaller tax of soft foap, because I have not taken in the part of both of which the revenue is defrauded, but left the one to balance the other. Of this, there goes a million sterling yearly, for tallow, to Russia or Spain, which I calculate by the proportion between the value of tallow and soap, viz. 2.

Q. Is there any thing fingular in the prefent state of Europe, which would call for an unusual demand from England, if soap could be got cheap?

A. Yes, the nations at war with England are in want of foap, because they cannot fend their ships to the Baltic for tallow. The French are so hard run, that they make a miserable soft soap (which

I have also made) from old rags, the refuse of wool *, and other impurities, contrived by Monfieur Chaptal.

Q. What are the political advantages of establishing a manufacture of soap from fish?

A. I reason in the following circle. The empire cannot substift without a navy; the navy without seamen; the seamen without a nursery of fisheries; and the fishers without markets. The French have struck us from our markets in Holland, Flanders, France, Spain, and the Mediterranean. But we should not feel the blow, if we had soap to supply even those nations; and it is impossible for them to do without it, as long as there are woollens, linens, cottons, and filk, to be washed in Europe.

2. What are the advantages of making foap from fifth, over falting it?

A. First, it requires no salt. Secondly, it employs more hands, coals, and other materials. Thirdly, it consumes the refuse of the fish which have been salted. Fourthly, it will consume the offal of whales, which at present are thrown to the dunghill, and also those myriads of fish which are driven on shore on the coasts of the British isles, by tempests, or the pursuit of voracious fish. Mr. Fordyce, of the House of Commons,

^{*} See Vol. VII. p. 346. of this work, which Sir John Dalrymple informs us first furnished him with the idea of these discoveries.

told me that he once bought fome tons of herrings, which had been driven on shore on his estate,
for a bottle of brandy. Lastly, the salting business can take place only in the fishing season,
when the fish are fresh; whereas the other will
have three working times. First, the fresh fish
will be salted. Secondly, those turned to putridity, even though three or four weeks old,
may be turned into oil. Thirdly, the resuse of
both, and the superabundance of fish which cannot be used in salting, or making oil, can be
turned into saponaceous matter, and made into
soap during all the rest of the year.

2. What are the proper places for fuch an establishment?

A. Cornwall, for pilchards; the Isles of Man or Anglesey, for cod; Shetland and the Firth of Forth, for herrings, where they are to be had for 2 l. a ton; but, above all, Hartlepool, if the fish be as numerous as I have heard, because, to that rendezvous on the east side of the island, might be brought the offal of the whales of Scotland, Newcastle, Whitby, Hull, and London.

Q. What do you know of the dog-fish for the

purpose of making soap?

A. I know nothing of dog-fish myself, but have been told by soap-makers, that they would make soap best. The duke of Athol told me, that they were in vast numbers round his Isle of Man, de-

stroyed the herrings, cod, and other fish, and were called the tyrant of the sea there. To which. Sir Joseph Banks added, that they were a real small shark, which not only destroyed the fish, but prevented fishers from getting sish, because they swallowed the bait and hooks, entangled the nets, and, when the fishers took them, they threw them away.

Q. Will the prefent duties require to be varied, fo far as relates to foap made of fish?

A. They will not, if the foap can be made as cheap as I think, otherwise the tax must be accommodated to the value.

Q. Do you think that a bounty fhould be granted on making foap from dog-fifh?

A. Commercial and political interests both require it.

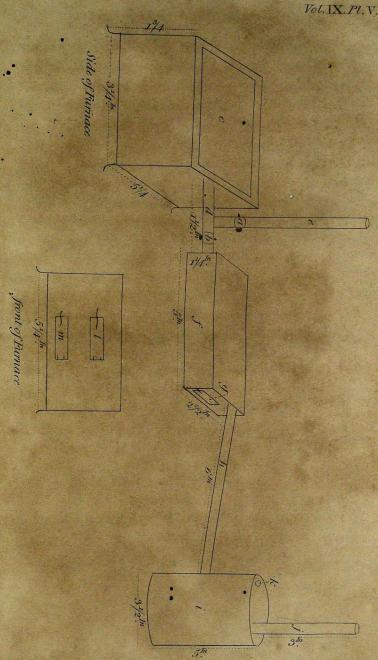

Q. Have you thought of any plan, whereby the conversion of fish into soap may be brought into public notice and use, without putting the public to expence, and with a faving to the public? What may that faving be, and on what do you calculate?

A. Government has works at different stations, carried on at its own expence, for bread, beer, portable soup, four-crout, &c. for the seamen. Now, my idea is, that they should have one work in Cornwall, and another in the North, or at least one somewhere, to make soap for the seamen and foldiers.

soldiers. A soldier is allowed 17s. and 4d. a year for washing; and, I believe, a feaman costs still more. A faving of 5s. a year on each man, at this rate, would be 100,000 l. a year. But this is a trifle, in comparison of preserving the health of the men, and therefore it would be better to give them more of the foap, and at a cheaper rate. It is known to the experience of every one, that clean woollen and linen contributes to the health, and confequently to the spirits, of men.

2. Have you a patent?

A. Having been careless in talking of our contrivances, I was afraid that some person might steal out a patent against us, use it as a monopoly, and turn it into a restraint against government itself. But my intention was, to furrender the patent to the public, if it interfered with the public interest, on getting some share of the faving, if there was a faving, and nothing, if there was none; and to leave the adjustment to Lord Liverpool, to whom alone the public owes my fuccefs, if I shall be successful, because he kept up my fpirits when almost every body else was prejudiced against the attempt.

XI. Specification of the Patent granted to Mr. William Murdock, of Redruth, in the County of Cornwall, Gentleman; for a Method of making (from the same Materials, and by Processes intirely new,) Copperas, Vitriol, and different Sorts of Dye or dying Stuff, Paints, and Colours; and also a Composition for preserving the Bottoms of all Kinds of Vessels, and all Wood required to be immersed in Water, from Worms, Weeds, Barnacles, and every other Foulness which usually does or may adhere thereto.

Dated May 2, 1791.

TO all to whom these presents shall come, &c. Now know ye, that I the said William Murdock, in compliance with the said proviso, do hereby describe and ascertain the nature of my said invention, and declare that the same is to be performed in manner following; that is to say, to make the yellow paint and dying-stuff, and for preserving ships' bottoms, and other wood immersed in water, from worms or other soulness, take any quantity of pyrites, (commonly called, Vol. IX.

in Cornwall, mundick;) which pyrites or mundick contains fulphur, arfenick, and ores of zinc; or take any minerals or ores which contain fulphur, arsenick, and ores of zinc: put the fame into a kiln, house, oven, cone, or heap, covered nearly close, and then set the fame on fire, admitting no more air than is fufficient to cause the said pyrites, mundick, or other minerals or ores, to burn; the fume or smoke of which must be conducted through a flue or conductor, from the top, fide, or bottom, of fuch house, kiln, oven, cone, or heap, into a receiver, in which receiver the fmoke is condenfed; by means of which condenfation, a fine yellow powder, fit for painting, dying, paying and preferving ships' bottoms, and all wood immerfed in water, is produced in the receiver. Or, take any quantity of ores of arfenick and fulphur, called pyrites, and commonly diffinguished, in Cornwall, by the name or appellation of mundick, and add thereto about onefixth part of the ores of zinc; which, being burned or condensed in manner before mentioned, produces a fine yellow powder, fit for painting, dying, and paying and preferving ships' bottoms, and all wood immerfed in water, as aforefaid; and, by increasing or leffening the quantity of ores of zinc added to the pyrites, various tints in the faid yellow powder will be produced, according

cording to the quantity of ores of zinc fo added to the pyrites. Or, take the ores of arfenick and fulphur, called pyrites or mundick, and burn and condense the same, as herein before mentioned; and this will also produce an inferior kind of yellow powder, but equally good with the before mentioned powder, for paying or preserving ships' bottoms, or other wood immerfed in water. And, to make green vitriol or copperas, take any quantity of the remains of the above calcined ores or minerals, after the fame are burned, and wash the same in water, and then place fuch water on the top, or any other part of the aforefaid kiln, house, oven, cone, or heap, whilft burning; and cause the water to evaporate by the heat of the ores or minerals, then burning in the faid kiln, house, oven, cone, or heap. Or, cause the said water to evaporate, by the heat of the fun, to a crystallizing point, and let the fame ftand for twenty-four hours, or longer, and cryftals of copperas or green vitriol will thereby be produced. In witnefs whereof, &c.

XII. Specification of the Patent granted to Mr. Christopher Wilson, late of Scarborough, in the County of York, Master Mariner, but now of Westminster; for a Method of combining Timbers, applicable to the Improvement of Naval Architecture, and all ponderous and large Works composed of Wood.

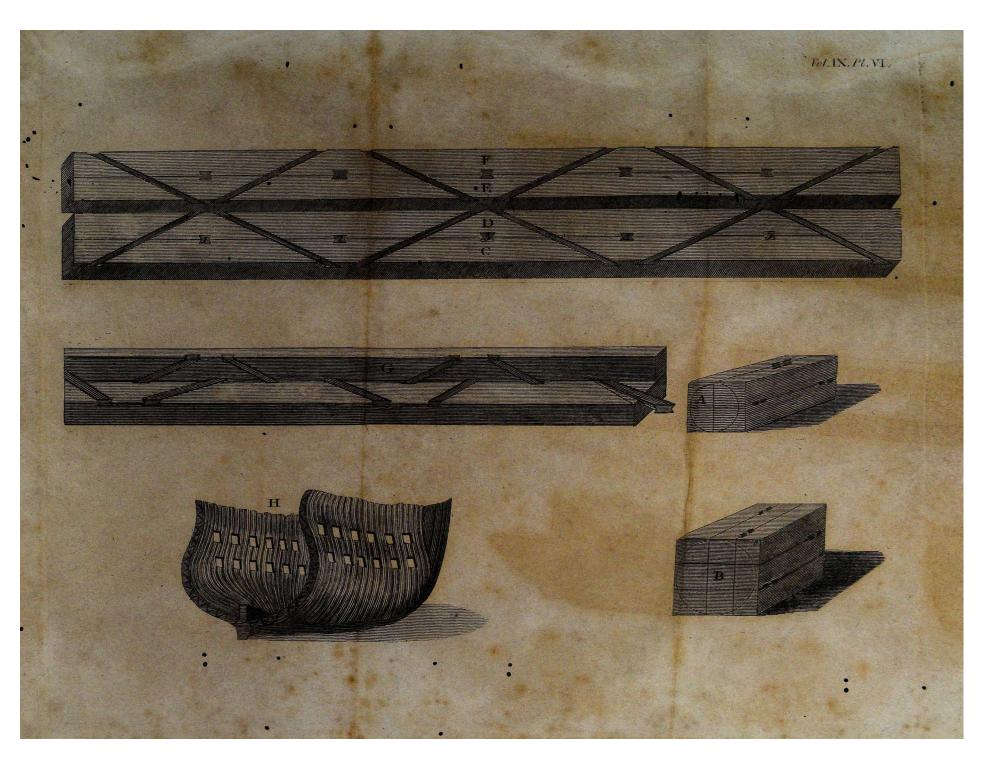

WITH A PLATE.

Dated Oct. 15, 1795.

TO all to whom these presents shall come, &c. Now know ye, that in obedience to the said letters patent, and the proviso therein contained, I the said Christopher Wilson do hereby describe and ascertain the nature of my asoresaid invention, and the manner in which the same is to be performed, in manner following; that is to say, to make masts, beams, or other works composed of wood, by combining timbers according to my said invention, sour or more pieces of timber are to be laid together, as represented by the figures marked A and B, contained in the plan or draw-

ing annexed hereto, (fee Plate VI.) both which fhew the end-view of the timbers; A, containing a combination of four, and B, of nine pieces of timber. To combine thefe, dove-tail or plain mortifes are to be cut, of a diagonal or inclined direction, as represented in the four timbers defcribed in the faid plan or drawing, and marked C, D, E, and F; half of each mortife to lie in C and D, and half in E and F; and fimilar mortifes are also to be cut through the right-angle junction of the four timbers, as represented therein by the numbers 1, 2, 3, 4, and 5; after which, the face C and D being laid on E and F. a dove-tail or plain flott, lock, or bolt, made of wood, is to be driven tight through each mortife, as exhibited by Figure G, in the faid plan or drawing, which reprefents three of fuch timbers, with the flotts, locks, or bolts, driven therein; the fourth being omitted, to shew the direction of the flotts, locks, or bolts, when the four are united: at the extenity of each flott, lock, or bolt, wedges made of wood or metal may be driven, where deemed necessary. By this method, numerous timbers may, in like manner, be combined, according and in proportion to the thickness and strength required; the same flott, lock, or bolt, in every inftance, being made to pass diagonally through the diameter of the whole. In producing

producing long pieces of timber by this method, the end-junctions must be fufficiently sloped, and lie over each other; and each union of ends must be so disposed of, throughout the whole length, that two end-joints may not be opposite or near each other; and the work may, where necessary, be rounded off, as described by the circles on the aforesaid figures A and B, in the said plan or drawing. The same method of driving slotts, locks, or bolts, diagonally into mortifes, may be practifed with great advantages between the ribs, timbers, or frames of ships, either in building or repairing, as exhibited by figure H in the faid plan or drawing; and likewise in every other part of shipping, and other large and ponderous works composed of wood, where strength and durability are required. In witness whereof, &c.

XIII. Specification of the Patent granted to Mr. WILLIAM WHITMORE, of Birmingham, in the County of Warwick, Engineer; for Improvements in Machines or Engines for weighing Waggons, and all other Carriages, as well as Goods or Wares, of any Kind whatever.

Dated Jan. 26, 1796.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said William Whitmore do hereby declare, that the following is a particular description of my said invention, and the manner in which the same is to be performed; that is to say, my method and principal improvements in making machines or engines for weighing waggons, and all other carriages, as well as goods or wares, of any kind whatever, (they being mostly placed in very damp places,) consists in securing the working parts from rust, and reducing the friction, and in making the fulcrums and bearings of such materials as are not liable to be injured

by rust; for which purpose, they are so contrived, that the faid fulcrums, with their bearings, are furrounded or inclosed within a box or trough. that has oil (or any other liquid or fubstance capable of producing the fame effect) put into the fame, and therewith filled, till the edges of the fulcrums are completely immerged in the faid oil or liquid. The whole should be then covered with leather, brafs, wood, or any other material, fo as to prevent dust or dirt getting into the boxes, whereby the edges are preferved to a great length of time, and the machine is more accurate, and less liable to be out of order. The levers in which the fulcrums are placed, fo as to fuftain the bridge, are made of various forms and materials, fuch as wood, caft-iron, wrought-iron, &c. &c. and the boxes are fastened on as the engineer may think best, so as they are capable of containing oil, or any other liquid, and in many instances applicable to old engines already erected. In witness whereof, &c.

XIV. Attempt to introduce a better Method of working Ships' Pumps than those in Common Use.

By Mr. Robert Clarke, Surgeon, in Sunderland.

WITH A PLATE.

THE object of this paper is, to fuperfede the mode of working common pumps by what is called a brake. To employ much reasoning, in proving the oppressive nature, and trisling effect, of an exertion which so many seamen and others have felt to their cost, and loudly complained of, may to some appear unnecessary; but, that we may not be charged, by others, with having taken too much for granted, it is proper to examine it particularly.

In the first place, the posture is weak, and much force is necessary to preserve it. It oppresses the man by over-stretching his loins, on one side, and incommodes respiration by the slexure of the other side. The motion of the shoulder-joint is too large. The muscles which act on the arm-bone at this joint are vastly disvolved in the supersymmetric proportionate.

proportionate to the charge they fustain, when the arm vibrates on the shoulder-joint as a centre, and the force is communicated by the hand. Besides this, the arms themselves are at one instant enseebled by being thrown above the head, at another battered to numbness by violent shocks downwards.

The changes of direction in the effort and fuftaining-force are continual and rapid, and the body is a continued dead weight upon the legs.

The action of rowing has not a defect I can discover. It is powerful to a surprising degree, and so well adapted to a man's ease, that he can continue it a great length of time without satigue. The motion is large, but is made up of easy motions in several joints. The velocity and resistance suit the muscles employed: very little sustaining force is needed, for the body is supported, and returns unloaded to its charge. To conclude: the posture is strong; the breathing free; and, happily for our purpose, it is the daily exercise of seamen, and may be applied to the working of ships' pumps with the mere intervention of a crooked lever.

Different circumstances having conspired to draw my attention to mechanical research at an early age, and my professional studies having added the affistance of anatomy, I have occa-fionally amused myself with investigating different modes

modes of applying manual force. I have felt myfelf diffatisfied with many; but with none fo much as with the common way of pumping ships.

I viewed the feaman cut off from the affiftance of his fellow-creatures; and his life, and often immense property, dependant on the efficacy of a pump. The best-constructed vessels are subject to numerous accidents which may render them leaky; and yet the only means of clearing them (large vessels excepted) is a pump, to be wrought by manual labour, applied in a manner the most oppressive and inessectual within the field of mechanics.

To introduce a better method, I have been at much pains and fome expence; but a fuccess highly grateful to me has followed my exertions. So long ago as the year 1792, I revolved the matter in my mind, and came to the decision, already stated, in favour of the action of rowing, as a mode of working ships' pumps. I made models and drawings, representing different ways of putting the contrivance in practice; but, from a variety of pursuits occupying the whole of my leisure, it was not until January, 1797, that an opportunity occurred of giving a trial to the plan.

A trial was then made on board the Archimedes, Captain James Hills, a fine new veffel, of 350

tons burthen, and belonging to this port. Two common pumps, with cast-iron chambers, five a inches and a half diameter, were placed in the usual manner: one was mounted with an ordinary brake; the other with the crooked lever, as represented in Fig. 1. (See Plate VII.) The pumps were repeatedly wrought, in the presence of feveral parties, confifting of people of confequence, and of judgement in these matters, with an uniform decifion in favour of the crooked lever: the pump to which it was affixed delivering more than twice as much water as the other, in a given time, and with less labour: each pump was worked by two men. The pumps were equally well made; and that one wrought by the brake delivered as much as any pump mounted in that way could do. The apparatus was by no means cumbersome upon deck. The vessel was snowrigged; and the feat, which was movable, hooked to the tri-fail-mast, and also to the combings of the pump. The whole of the working parts, and the feat, were kept below deck, when not employed.

Innovations in any line are cautiously admitted: in most cases this is proper; with nautical men perhaps peculiarly so. A doubt prevailed lest the tossing of the ship, when at sea, and exposed to the breakers passing over her, might not destroy

the advantage of the new method: this doubt, however, was foon removed.

The first voyage the vessel made was to the Baltic; she had a very stormy passage, and made much water. Here the character of the invention became settled; for, after repeated trials, the crew gave it so decided a preference, that, when one pump only was to be wrought, they used this; and, when both pumps were needed, they strove who should get to the new one. The impression made by sufferings on the minds of seamen are proverbially transient: this remark, however, has its exceptions; for the report of the above-mentioned ship's crew did as much credit to their hearts, as it gave unalloyed pleasure to my feelings.

EXPLANATION OF THE FIGURES.

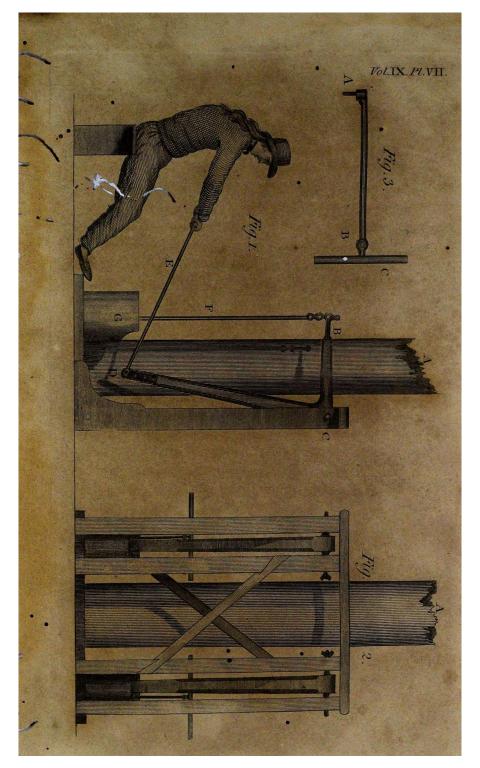

(See Plate VII.)

Fig. 1. represents a starboard side-view of the apparatus. A, the main-mast. B C D, the crooked lever. E, the rod of the handle, at which two men, seated, draw as if rowing. F, the spear of the pump. G, the pump, which, for this

this proportion of lever, and quantity of moving power, is five inches and a half diameter in the working-chamber, and eighteen feet lift.

Fig. 2. reprefents the same apparatus, seen from before. A, the main-mast. Both pumps are seen in this view, where references are omitted, as unnecessary.

Fig. 3. exhibits the handle, as it appears when viewed from above. A, a flud, which, being inferted into one of the holes of the crooked lever, at D, receives a fore-lock. B, a joint in the handle, by means of which the wooden crosshead C, may be folded close to the crooked lever, when not in use.

XV. On a new Method of preparing a Test-Liquor, to she wife Presence of Acids and Alkalies, in chemical Mixtures. By JAMES WATT, Esquire, of Birmingham, Engineer.

From the Philosophical Transactions of the Royal Society of London.

THE fyrup of violets was formerly the test of the point of saturation of mixtures of acids and alkalies which was principally used; but, since the late improvements in chemistry, it has been found not to be sufficiently accurate, and the infusion of turnsol, or of an artissical preparation called litmus, has been substituted in the place of it.

The infusion of litmus is blue, and becomes red with acids. It is sensible to the presence of one grain of common oil of vitriol, though it be mixed with 100,000 grains of water; but, as this infusion does not change its colour on being mixed with alkaline liquors, in order to discover whether a liquor be neutral or alkaline, it is ne-

ceffary

ceffary to add fome vinegar to the litmus, fo as just to turn the infusion red, which will then be restored to its blue colour, by being mixed with any alkaline liquor. The blue infusion of litmus is also a test of the presence of fixed air in water, with which it turns red, as it does with other acids.

The great degree of fensibility of this test would leave very little reason to search for any other, were there reason to believe that it is always a test of the exact point of saturation of acids and alkalies, which the following sact seems to call in question.

I have observed, that a mixture of phlogisticated nitrous acid with an alkali, will appear to be acid, by the test of litmus, when other tests, such as the infusion of the petals of the scarlet rose, of the blue iris, of violets, and of other slowers, will shew the same liquor to be alkaline, by turning green so very evidently as to leave no doubt.

At the time I made this discovery, the scarlet roses, and several other flowers whose petals change their colour by acids and alkalies, were in flower. I stained paper with their juices, and sound that it was not affected by the phlogisticated nitrous acid, except in so far as it acted the part of a neutralizing acid; but I sound also, that

paper stained in this manner, was by no means fo eafily affected by acids of any kind as litmus was, and that in a fhort time it lost much of that degree of fenfibility it poffeffed. Having occasion, in winter, to repeat some experiments in which the phlogisticated nitrous acid was concerned, I found my stained paper almost useless. I was therefore obliged to fearch for fome fubftitute among the few vegetables which then existed in a growing state; of these, I found the red cabbage (braffica rubra) to furnish the best test, and, in its fresh state, to have more sensibility, both to acids and alkalies, than litmus, and to afford a more decifive test, from its being naturally blue; turning green with alkalies, and red with acids: to which is joined the advantage of its not being affected by phlogisticated nitrous acid, any farther than it acts as a real acid.

To extract the colouring matter, take those leaves of the cabbage which are freshest, and have most colour; cut out the larger stems, and mince the thin parts of the leaves very small; then digest them in water, about the heat of 120 degrees, for a few hours, and they will yield a blue liquor, which, if used immediately as a test, will be found to possess great sensibility. But, as this liquor is very subject to turn acid and putrid, and to lose its sensibility, when it is wanted to be preserved

for future use, the following processes succeed the best.

on paper, and dry them in a gentle heat. When perfectly dry, put them up in glass bottles, well corked; and, when you want to use them, acidulate some water with vitriolic acid, and digest or insuse the dry leaves in it until they give out their colour; then strain the liquor through a cloth, and add to it a quantity of sine whiting, or chalk, stirring it frequently until it becomes of a true blue colour, neither inclining to green nor to purple: as soon as you perceive that it has acquired this colour, filter it immediately, otherwise it will become greenish, by longer standing on the whiting, or chalk.

This liquor will deposit a small quantity of gypfum, and, by the addition of a little spirit of wine, will keep good for some days; after which, it will become a little putrid and reddish: if too much spirit is added, it destroys the colour. If the liquor is wanted to be kept longer, it may be neutralized by means of a fixed alkali, instead of whiting or chalk.

2. But, as none of these means will preserve the liquor long without requiring to be neutralized asresh, just before it is used; and as the putrid and acid fermentation which it undergoes, and perhaps the alkalies or spirit of wine mixed with it, seem to lessen its sensibility; in order to preserve its virtues, while it is kept in a liquid state, some fresh leaves of the cabbage, minced as has been directed, may be insused in a mixture of vitriolic acid and water, of about the degree of acidity of vinegar; and it may be neutralized, as it is wanted, either by means of chalk, or of the fixed or volatile alkali. But it is necessary to observe, that if the liquor has an excess of alkali, it will lose its colour, and become yellow, from which state it cannot be restored; therefore care should be taken to bring it very exactly to a blue, and not to let it verge towards a green *.

By the same process, I have made a red infusion of violets, which, on being neutralized, forms at present a very sensible test; but how long it will preserve its properties I have not yet determined. Probably the coloured insusions of

Q 2

other

^{*} Since writing the above, I have found that the infusions of red cabbages, and of various flowers, in water acidulated by means of vitriolic acid, are apt to turn mouldy in the fummer feason; and also, that the moulding is prevented by the addition of spirit of wine. The quantity of spirit which is necessary for this purpose, I have not been able to ascertain; but I add it by little at a time, until the progress of the moulding is prevented.

other flowers may be preserved in the same manner, by the antisceptic power of the vitriolic acid, so as to lose little of their original sensibility. Paper fresh stained with these tests, in their neutral state, has sufficient sensibility for many experiments; but the alum and glue which enter into the preparation of writing-paper, seem, in some degree, to six the colour; and paper which is not sized, becomes somewhat transparent, when wetted, which renders small changes of colour imperceptible; so that, where accuracy is required, the test should be used in a liquid state *.

^{*} I have found that the petals of the fearlet rofe, and those of the pink-coloured lychnis, treated in this manner, afford very fensible tests.

XVI. On the Action of Metallic Oxides and Earths upon Oils, in low Degrees of Heat. By Mr. PETER HENRY.

From the Memoirs of the Literary and Philosophical Society of Manchester.

THE high degree of colour possessed by many of the expressed and satty oils rendering them unsit for several uses in the arts, it appeared to be a desirable object to discover a mode of depriving them of their colouring particles.

For this purpose, the following experiments were instituted.

1. Two ounces of spermaceti-oil were digested with one drachm of white arsenick, in a heat of 180° of Fahrenheit, during six hours; and left to stand till morning. The oil was then perfectly clear and colourless, and much heavier than it was previous to the experiment: a great part of the arsenick, however, remained undissolved, at the bottom of the digesting vessel.

2. Two ounces of linfeed-oil were digested with one drachm of white arsenick, under the same circumstances with the former. In the morning,

very

very little alteration being perceived in the mixture, it was exposed to a somewhat greater heat. In two hours the oil appeared brighter and clearer, much of the arfenick being diffolved; but it vet retained a great part of its original colour. There was a confiderable deposition of mucilage; the arfenick which remained undiffolved being tinged of a light yellow colour.

- 3. Green olive-oil was treated in a fimilar manner with the spermaceti-oil, and attended with the fame refult.
- 4. Thick train-oil was digested with a drachm and a half of white arfenick. No great alteration was observed in the colour of the oil, though it was evidently rendered clearer and more limpid.

When the oils were at the greatest heat, a brisk effervescence took place, in all of them, upon flaking the bottles, but immediately discontinued on the arfenick being suffered to subfide. When poured on the hands, they inftantly shrivelled the ikin, and were either absorbed, or soon dried up. Two phials of No 1 and 2, being left exposed to the action of air and light, for fome months, were not in the least changed.

As it was evident, that a confiderable portion of arfenick was diffolved in all the foregoing experiments, I wished to see if it could be precipitated, and at the fame time the oils be left pure, and deprived of colour; though with no great

hopes

hopes of fuccess, from the known property of the mineral acids to render oils thick and discoloured.

5. Part of N° 1 being poured into a phial, three or four drops of firong vitriolic acid were added. The arfenick immediately precipitated, leaving the oil as pure and colourless as before.

6. The fame quantity of vitriolic acid being added to N° 2, 3, and 4, the arfenick was in like manner precipitated. N° 2 feemed even clearer than before the addition of acid.

7. Nitrous acid being added, in the fame proportion with the vitriolic, the colour of all the oils was inftantly changed to a dark brown, except the spermaceti oil, which was not much affected; the train and linseed oils suffering the greatest change. In all of them a slight effervescence took place.

8. Marine acid occasioned a precipitation, which foon redisfolved, in all of them.

9. Both the fixed alkalies immediately coagulated the oils; the water in which the folution of alkali was made, fubfiding to the bottom of the veffel, along with the arfenick.

10. Three ounces of spermaceti-oil were digested with one drachm of litharge, during fix hours, in about 200° of Fahrenheit. The oil became much clearer than before the experiment, but not near so colourless as when treated with arsenick: the litharge was changed to a white colour.

colour. Part of the oil being poured off, and the heat afterwards increased, it soon became thick and high coloured.

11. Linfeed-oil, exposed to the same degree of heat, under similar circumstances, underwent the

fame changes.

12. Train-oil was little affected in low degrees of heat, but, in higher degrees, became difcoloured:

13. A few drops of vitriolic acid being added to a portion of No 10, before the heat had been increased, the litharge was precipitated, and the oil left pure and clear, though not quite colourless.

- 14. Vitriolic acid being added to the linfeed and train oils, N° 11 and 12, a very small precipitation of the litharge took place; probably owing to the heat not having been sufficiently great to dissolve it in large quantities, which had been found to be the case with the same oils, when digested with arsenick.
- 15. Nitrous acid, when added, instantly changed the colour of all three (N° 10, 11, and 12,) to a dark brown; N° 11 and 12 became thick and glutinous.
- 16. Marine acid precipitated the litharge. Upon being left to ftand, the linfeed and train oils affumed a much darker hue than they had previous to the addition of the acid.
- 17. Alkalies coagulated the oils, as in the former experiments with them.

- 18. Two ounces of spermaceu-oil and half a drachm of red-lead, were digested during eight hours. The oil seemed not in the least changed; but a small quantity of the lead remained suspended, and gave it a slight pink cast. The heat, the next day, was gradually increased, with as little success, till the oil was brought to nearly a boiling heat; it then became dark and discoloured.
- 19. Linfeed-oil was tried in the fame proportion, with the like refult.
- 20. Train-oil was treated in the same mode as the others, with one drachm of red-lead. On increasing the heat, it formed a very thick dark coloured mass.
- 21. White-lead, and the oxide of copper which is formed upon the distillation of acetated copper, had the same effect with the red-lead. But less of the oxide of copper appeared to be dissolved than of the oxides of lead.

Not meeting with the fuccess I was at first led to expect, from the digestion of the oils with the metallic oxides, I submitted them to the action of different pure aërated earths, under the same degrees of heat.

22. Two ounces of spermaceti-oil and one drachm of the earth of alum, precipitated from a solution of alum by the vegetable fixed alkali, were placed in a sand heat, of from 180° to 190° of Fahrenheit, and suffered to remain there during Vol. IX.

three hours. The oil became clear and coloutless, the gluten having precipitated with the earth to the bottom of the vessel.

- 23. Two ounces of linfeed-oil and one drachm and a half of pure clay, were subjected to the same degree of heat as the spermaceti-oil. This oil likewise became very clear, and much less coloured: a considerable deposition of mucilage was observed upon the surface of the clay. The combination of the mucilage with the linfeed-oil, appeared to be much stronger than that of the spermaceti-oil with its gluten.
- 24. Train-oil was likewife rendered much purer by digeftion with the same earth; but was in no degree equal either to the spermaceti or linseed oils.
- 25. Both aërated and pure magnefia precipitated the mucilage whilft the oils continued warm; but, as they cooled, the mucilage and magnefia rofe, and mixed again with the oils.
- 26. Ten grains of pure calcareous earth being added to one ounce of each of the oils, in the cold, turned them thick, and dark coloured.
- 27. Aërated calcareous earth had little effect upon the oils, either heated or cold.

In all these experiments with the earths, not the smallest particle seemed dissolved, as, on the addition of any of the acids, they instantly changed to a very dark colour. Those oils to which

which the nitrous acid was added, became much darker than those in which the metallic oxides had been digested, and to which the same addition had been made.

It is well known, that oils obtain the property of drying more quickly, by being boiled, either alone, or in conjunction with metallic oxides, and argillaceous earths. Oil, according to M. Lavoifier, confifts of hydrogen or the basis of inflammable gas, and carbone, the balis of carbonic acid or fixed air. The metallic calces confift of the metal united to oxygen or the bafis of pure air. According to this fystem of chemistry, the metal, when boiled in oil, gives up oxygen to it, while the mucilage of the oil unites to the metal. Itfeems therefore probable, that in high coloured oils the carbone is superabundant; and that, by digefting the calces of metals in a lower degree of heat, a part of the oxygen of the calx may combine with the fuperfluous carbone, and, forming carbonic acid, tend to diveft the oil of its colour; while the oxide, attracting the mucilage, may contribute to the fame end.

How far this theory may apply to the explanation of the foregoing experiments, I do not pretend to determine. It is remarkable, however, that one of the earthy fubstances, viz. the alumine, which is not known to contain either oxygenious or carbonic gas, decoloured the oils more R 2

powerfully

powerfully than most of the metallic oxides, and equally with any of them. This earth has a ftrong. attraction for colouring matter, and on this property depends its use in dying.

But, on the supposition that the above theory is just, it may be expected, not only that oils may be deprived of colour, but that rancid oils may be restored to sweetness, by the metallic oxides. My father formerly found * that rancid oil, exposed to itreams of carbonic gas, was sweetened. The fame effect may be produced by the fame gas, formed in the process; and indeed, though I was not particularly attentive to this circumstance, I thought the train-oil was diminished in rancidity; and the spermaceti-oil, which was kept for feveral months after exposure to heat, continued fweet.

Another circumstance, worthy of remark, is, that though concentrated vitriolic acid, on addition to oils, blackens them, and gives out a fulphureous fmell; yet, when dropped into oils in which the metallic calces have been digested, it combines with the calces, and precipitates them, without either discolouring the oils, or changing their odour.

^{*} Henry's Experiments and Observations, page 129.

XVII. Continuation of M. RIBAUCOURT'S Observations on the Composition of Writing-Ink.

(From Page 70.)

IT is faid, that fulphate of iron causes those stuffs which are dyed with it to feel rough to the touch, and that it also corrodes them. Should not these defects be rather attributed to the first coarse precipitate already spoken of?

Its coarfeness is sufficient evidence that it cannot penetrate to the internal pores of the fibres of the wool. It appears that all it can do is, to attach itself to their surface, and to lodge itself, as it were, in the intervals left in the texture of the cloth; and that it wears them, on account of its hardness. For, if we admit, as we cannot help doing, that the sulphate of iron has been decomposed, and that its acid is saturated with the gallic earth, we can no longer consider its being capable of corroding the stuffs which are dyed with it.

The fineness of the two following precipitates, and particularly of the third, which is also of a blacker

blacker colour than the two first, seems to me also to explain why the black dye used by hatters (which, with respect to the proportions if its ingredients, is, as M. Berthollet has remarked, rather an ink than a dye) will not dye silk at first; but dyes it very well, after a certain number of hats have been passed through it.

I shall not enter more largely into this subject; it is sufficient for me to have pointed out in what manner my discovery may be applied to the theory of dying black. By attentively considering the matter, affished by the excellent observations of M. Berthollet, which agree perfectly well with mine, it appears to me easy to form an exact idea of the effect of galls on the sulphate of iron, in the black dye; not only when that dye is applied to wool, but also when it is applied to filk: and I think, that we may perhaps be able to apply that dye to thread and cotton, with more effect than has hitherto been done, and without being obliged to have recourse to a solution of iron in vinegar.

The discovery of the forementioned earthy falt in galls, serves to explain the effects they produce when they are used in preparing wool, filk, thread, and cotton, for the black dye.

I shall now return to ink, and shall give my opinion respecting the theory of the phænomena which take place in the decomposition of sulphate

of iron by galls. By taking the weight of my three precipitates collectively, and comparing their colours, I hope to be able to shew, that all the acid of the sulphate of iron was united to all the gallic earth; and that all the oxide of that metallic salt was precipitated of a black colour, by the colouring-matter of the galls: in short, that ink owes its colour to this precipitate, which is not dissolved, but merely suspended, in the liquor.

But, before I enter into this explanation, I think it proper to make fome preliminary observa-

In the first place, it must be remembered, that the decoction of one pound of galls, when a solution of potash is poured into it, gives six ounces of earth.

Secondly, that fix ounces of oxide are also obtained from one pound of sulphate of iron, treated in the same manner.

Thirdly, that water alone, when employed in fufficient quantity, decomposes sulphate of iron. Experience has shewn me, that fix hundred and eighty parts of water completely decompose one part of this metallic salt.

Now it appears, that my three precipitates, when united weighed, eighteen ounces; and the precipitate which I obtained from two ounces of each of these ingredients weighted eighteen drachms.

From this calculation it follows, first, that the fix ounces of gallic earth, in combining with the fulphuric acid, absorbed fix ounces of it, with which they formed a felenite, the greater part of which was immediately precipitated, on account of its infolubility in water; for it appears, that there remained in the liquor only half an ounce, or one twenty-fourth of the whole.

Secondly, that the fecond and third precipitates confifted of oxide of iron, almost pure: being united only to the fore-mentioned small portion of selenite, and to the colouring-matter of the galls. The appearance of these precipitates, and their different degrees of friability, even inclined me to believe that the latter was entirely free from it; but I did not make any experiments to determine the matter.

The different degree of intenfity I observed in the colour of the precipitates, is very important, and helps to confirm what I have here advanced.

The greyish-blue colour of the first precipitate shews that it consists only of selenite, which has taken that colour because it was deposited in a coloured liquor; and also because it has, in its precipitation, carried off a finall portion of coloured oxide of iron.

As the fecond precipitate is of a purplish-blue colour, and the third of a blue more inclining to black than the fecond, I conclude that the latter is the most pure; since it is only oxide of iron

which

which receives the black colour from galls: and I fuppose that the others are more blue, merely because they are composed of black and white, or that their blackness is more diluted.

M. Monnet examined the precipitate of fulphate of iron by galls, or, to use his own words, by the aftringent principle; he found it to be of a very beautiful dark-blue colour, and thinks it might be advantageously made use of in painting.

Although the formation of the first precipitate may be eafily explained, by the union of the fulphuric acid with the gallic earth, from which there refults a felenite that is infoluble in water, that is by no means the cafe with respect to the two others. I first explained them, by the decomposition of the new ferruginous gallic salt by water; but, having more fully confidered this explanation, I thought that the colouring-part which had combined with the oxide of iron, might also be one of the causes of its precipitation, in concurrence with the former.

I thought I could not better endeavour to clear up this doubt, than by attempting the decompofition of fulphate of iron by pure water alone; and, after feeking to determine the exact proportion of water requifite for that purpose, I found, as I have already frated, that one part of this falt could not be completely decomposed, by less than fix hundred and eighty parts of pure water. Comparing,

VOL. IX.

Comparing, afterwards, the precipitate formed in the manner just mentioned with the third of those produced by means of galls, I observed that the one obtained by water only was of a yellow colour, dissolved easily and completely, (with effervescence, but without the affistance of heat,) in the nitric, sulphuric, and acetous acids, particularly before it had been dried; whilst the other, which, as I before observed, was of a blackish colour, was not attacked by those acids, unless affisted by heat, and was only partially dissolved therein, with great difficulty and flowness.

The colour of the first precipitate, the ease with which it was diffolved in a new acid, and the effervescence which accompanied its diffolution, persuaded me that it had been separated from its acid by a superabundant quantity of oxvgen, which it had taken in the water; and I also thought it fair to suppose, that the other had, on the contrary, been precipitated by a superabundant quantity of phlogiston, which the colouring principle of the galls had given to it: that is to fay, that one had quitted its folvent, because the oxygen of the water had completed its calcination and dephlogiffication, which the fulphuric acid had begun; and that the other had feparated from its folvent, because it again met with the principle of inflammability in the colouring-matter of the galls:

galls: also that the iron was restored, and even surcharged with phlogiston; in short, that it was brought into a state similar to that in which it exists in Prussian blue.

The blue colour of my precipitates, and the phænomena which, as we have just feen, they present with acids, led me to perceive this analogy (and particularly that of the two last) with Prussian blue; to convince myself of it, I determined to expose them to a gentle fire, with an alkaline liquor.

The first precipitate, as soon as it was penetrated with this liquor a little warmed, effervesced pretty strongly, which announced the decomposition of the selenite; the liquor acquired a reddish hue.

The effervescence of the second was hardly to be perceived, and the colour of the liquor became more deep.

I observed no effervescence at all in the third and the colour of the liquor was nearly as deep as that of the preceding.

I repeated the fame operation upon the third, precipitate, with ammoniac or volatile alkali; the phænomena were the fame as before.

I then poured fome drops of a folution of fulphate of iron upon these liquors, after they were filtered and diluted with water, and I obtained very beautiful Prussian blue.

S 2 I had

I had no longer any doubt respecting the analogy of my precipitates with Prussian blue; and the above sact confirms my theory. It was very clear, from these experiments, that the first precipitate was a selenite, as I had supposed, since it effervesced with alkaline liquors, and gave them but a very faint colour, in comparison of that from the two others. It appeared also, that the second precipitate still contained selenite, as it produced a slight effervescence; and that, if the third contained any of that substance, it was at least in very small quantity, since it caused no sensible effervescence. The intensity of colour was also in proportion to the degree of homogeneity of the matter of the precipitates.

Lastly, these experiments shew, that ammoniac may become faturated with Prussic acid, and form Prussian blue, in the same manner as takes place with potash and soda.

These facts being established, the phænomena respecting the decomposition of sulphate of iron, by a decoction of galls, explain themselves; so also does the cause of the black colour of ink, and that of the black dye.

As foon as a folution of fulphate of iron in water is mixed with a decoction of galls, the fulphuric acid acts upon the earthy basis of the gallic falt, and forms a selenite, which, being insoluble

luble in water, is precipitated. On the other hand, a portion of the oxide of iron, being quitted by its folvent, charges itself with the colouring matter of the galls, and, on account of its great lightness, remains suspended in the liquor, which it renders opaque, and of a black colour.

Laftly, the gallic acid either diffolves a part of the superfluous oxide of iron, or else remains free in the liquid; for, according to what I have before observed, there is no probability that it can possibly act upon the iron, which is saturated with colouring matter.

This explanation will be ftill farther confirmed by subsequent experiments.

Of the Effect of Campeachy or Logwood, with refpect to black Colours in general, and particularly with respect to Ink.

Lewis confiders logwood as a very useful ingredient in making ink, the colour of which, he says, it very much improves, without giving it a disposition to sade.

He fays also, that sulphate of iron and galls, in whatever proportions they are employed for making ink, produce only different shades of brown, but that logwood gives blackness to the liquor.

A de-

A decoction of logwood contains no falt with an earthy basis, as a decoction of galls does; it is, therefore, not by decomposing sulphate of iron, by this principle, that the logwood acts in producing a black colour, but by charging the oxide of iron with its colouring matter, (which it is known to contain in great abundance,) in a degree to which we cannot arrive without its assistance, except by very much augmenting the quantity of galls; too great a proportion of which, as we shall see hereafter, is detrimental to ink.

I have faid, that a decoction of logwood contains no falt with an earthy basis; I shall now prove that it does not.

If, into a decoction of two ounces of this wood, a folution of two ounces of fulphate of iron be poured, and the mixture be then diluted with water, fo that the whole quantity of liquor confift of forty pounds, after ftanding twenty-four hours, a precipitate of a purple colour, very much inclining to black, will be produced, weighing three quarters of an ounce; the liquor above the precipitate will have entirely loft its colour.

The weight of the precipitate, which is only that of the oxide contained in two ounces of fulphate of iron, shews that no selenite is formed in this operation; consequently, that the decoction

of logwood has not precipitated this oxide by the action of an earthy fubstance upon the sulphate of iron, but merely by the action of its colouring matter, joined to that of the water.

I fay that the colouring matter has concurred with the water in caufing the precipitation; because, if there had not been a great quantity of water, a part only of the oxide would have been precipitated; if the quantity of water had been very small, there would have been scarcely any precipitate.

If this experiment be repeated, with the addition of two ounces of galls to the fore-mentioned quantities of logwood and fulphate of iron, the precipitate will weigh two ounces and a quarter; that is, will weigh no more than that obtained from a mixture of fimilar quantities of galls and fulphate of iron, without any logwood; but it will be more black than that from those two ingredients alone.

Logwood, therefore, acts upon fulphate of iron in a different manner from galls. Its effect is, to furnish to the oxide of iron a great furcharge of colouring matter; which, by rendering it infoluble in acids, forces it to quit the fulphuric acid, and, at the fame time, hinders it from being acted upon by the gallic acid. This acid otherwise would not fail to rediffolve it, (at least in a quantity proportioned to its action, and its de-

gree of concentration,) when it became separated from its first solvent.

Logwood very much improves both the beauty and the colour of ink, for many reasons.

First, because the precipitate which it forms with sulphate of iron is more black than that formed by galls.

Secondly, because the oxide of iron must be more black, in proportion as it is more charged with colouring matter.

Thirdly, because, in consequence of what has been above stated, the oxide of iron is more disposed to quit its solvent, and less disposed to be redissolved by the gallic acid, in proportion as it is more surcharged with colouring matter: now, if the oxide of iron were dissolved by any kind of acid, the solution would be transparent; it would neither have the opacity, nor the colour, of ink. No solution of any salt is opaque, nor is any solution of iron of a black colour; these properties of ink are therefore owing to the separation of the oxide from its solvent, and to the suf-pension of its precipitate in the liquor.

Lewis adds, that logwood improves the colour of ink, without disposing it to fade. He might have faid, that it not only does not dispose the colour to fade, but that it preserves it; since the more the oxide of iron is charged with colouring matter, the more it is enveloped and preserved

from

from the action of the air; from which it follows, that it keeps its blackness better, when applied upon paper.

Consequently, logwood is a very useful ingredient in ink; and those inks which are made without it have neither the blackness nor the permanence of colour which form the principal perfections of this liquor. Yet, notwithstanding these advantages, it is an ingredient in very few of the formulæ for ink: I have found it in none but in Lewis's.

It is impossible, however, to make ink with logwood alone; because, as this wood does not furnish any salt with an earthy basis, it would not decompose the sulphate of iron in such a manner as to produce a sufficient quantity of black precipitate; and, more especially, because it would not furnish a basis with which the sulphuric acid could unite, which acid, remaining free in the liquor, would act upon the paper and corrode it,

Of the Effect of Sulphate of Copper (blue Vitriol)
upon Ink.

Sulphate of copper is ftill less frequently used in making ink than logwood. Amongst a great number of formulæ that I have collected, I have Vol. IX.

found but one in which it entered; and yet it may be employed with great advantage, not, as many perfons (according to Lewis's account) have recommended, in place of fulphate of iron, but joined with it. This is contrary to Lewis's observation, who says that different proportions of pure sulphate of copper, added to the sulphate of iron, produced inks which were not equal to those prepared with the latter substance only.

The effect of the fulphate of copper upon the black colour is, to make it more dark, and to render the colour permanent. This last-mentioned property of preparations of copper was known to the antients: it is called by them coloris alligatio.

There is no doubt that fulphate of copper is of great advantage to ink; and, if Lewis found that it was detrimental to it, it was probably because he made use of too great a proportion of it.

Of the Effect of Acetite of Copper (Verdegris) upon Ink.

Some persons, probably because verdegris renders black dyes more deep, have thought right to use a certain quantity of it in their compositions for ink, but the black colour produced thereby,

thereby, which appears to be permanent uponwool, is, as Lewis has observed, apt to fade when applied upon paper. The colour of the ink is indeed much more dark when the writing is first made; but it is not permanent, and grows rusty much sooner than when verdegris is not made use of.

It may perhaps be asked, if the use of sulphate of copper tends to fix the colour of ink; and even to strengthen it, why does not the acetite of copper produce the same effect?

The reason is, that the first, being soluble in water by itself, does not interfere with the affinities of the acids to the earthy and metallic substances of the other ingredients, and that it is decomposed by the same causes, and at the same time, as the sulphate of iron; also, that the two oxides are precipitated together and unite; whereas the copper of the verdegris can only be partially precipitated, with the coarser particles. It is probable that nothing is decomposed by the water, except the salt formed of that portion of oxide of copper which is kept in solution by the acetous acid; the precipitate of which is too small in quantity to produce the effect expected from it.

Verdegris, therefore, ought not to be used in making ink, sulphate of copper being preserable to it.

T 2 On

On the Effett of Gum.

Gum is an effential ingredient in the composition of ink: its effect is, to give consistence to the fluid, and to keep in suspension the ferruginous precipitate; either by preventing it from forming in particles sufficiently gross to fall to the bottom by their own weight, or by retarding the fall of the particles after they are formed.

It also hinders the ink from spreading on the paper; so that every stroke of the pen deposits a greater quantity of black matter, and consequently a greater body of colour.

It likewise prevents the ink from finking into,

or paffing through, the paper.

And it envelops the colour in a kind of varnish, which not only covers it, and defends it from the access of air, but also gives it a shining appearance.

All the formulæ prescribe gum-arabic; but every other kind of gum (even those from our own trees) may be used in its place. Gum, of one kind or other, is necessary whatever the other ingredients may be.

On the Effect of Sugar.

Authors are not fo well agreed on the neceffity of the use of sugar, in the composition of ink, as on that of gum; it enters, however, into a great number of formulæ.

Sugar is much less efficacious than gum, either in enveloping the colour, or in preventing its precipitation; it even hastens the precipitation of some portions of the colour, and renders the ink very slow in drying. The shining colour it gives the ink does not compensate for these defects; indeed gum makes it shine almost as much.

It is therefore not in order to envelop the colour, nor to prevent its precipitation, that fugar is made use of in the composition of ink; it has certainly neither of these properties, both of which belong to gum.

There is hardly any doubt that it haftens the precipitation of some portions of the colour; and it is still more certain that it makes the ink dry with difficulty; this effect, however, does not take place to any great degree, unless too large a quantity of sugar be made use of.

In short, it is not fugar, but gum, that is the proper ingredient to give a shining quality to ink. The effect of sugar is only to make it flow

more freely from the pen; and, if it has been found necessary to increase the quantity of the fugar, in those inks which were desired to shine very much, it was because a great quantity of gum was put into them, and therefore sugar was found necessary, in order to make them flow.

Upon the whole, fugar may be confidered as an ingredient necessary to the perfection of ink.

On the Effett of Alum.

Of all the ingredients that have been made to enter the composition of ink, there is not one which is so prejudicial to the beauty of its black colour as alum; the effect of this salt being always to change the black colour, more or less, to purple.

Alum, therefore, ought to be excluded from the composition of ink.

TO BE CONCLUDED IN OUR NEXT.

XVIII. Lift of Patents for Inventions, &c.

(Continued from Page 72.)

ROBERT JOHNSON, of Greek-street, Soho, in the county of Middlesex, Chemist and Apothecary; for a medicine, (known by the name of Whitehead's Essence of Mustard,) for the cure of rheumatisms, and other complaints. Dated March 30, 1798.

WILLIAM DEVERELL, of Widcomb, in the county of Somerfet, Millwright; for a new-invented pump, or pump-work. Dated April 5,

1798.

WILLIAM SELLARS, of the city of Bristol, Manufacturer of Spinning-Machines; for a new invention in making and working machines for preparing and spinning wool, cotton, flax, hemp, and various other materials. Dated April 18, 1798.

FRANCIS HOLLICK, of Birmingham, in the county of Warwick, Curry-comb maker; for a new-invented art of affixing, in feveral ways, an iron or other comb to the edge, or on the outfide.

outside, of a curry-comb. Dated April 18, 1798.

JOHN EDWARDS, of Bristol, Mathematical Instrument maker; for an apparatus of mathematical instruments, for the better ascertaining the geographical position of vessels at sea. Dated April 18, 1798.

THOMAS ROWNTREE, of Great Surrey-street, Blacksriars-Bridge, Engine maker; for a method of applying fire, for the purpose of heating boilers and other vessels where heat is required. Dated May 1, 1798.

JOSEPH BRAMAH, of Piccadilly, Engineer; for an improvement in locks for doors, cabinets, &c. and also in the keys by which they are locked and unlocked. Dated May 3, 1798.

John Daniel Belfour, of Elfineur, in the kingdom of Denmark, Merchant; for improvements in the operation or working part of a machine formerly invented by him, for making and manufacturing ropes and cordage. Dated May 3, 1798.

PETER BOILEAU, of Bruton-street, in the parish of St. George, Hanover-square; for manufacturing straw into hats, bonnets and other articles, in a manner, and to produce an effect, never before attempted. Dated May 3, 1798.

IX. Specification of the Patent granted to MAT-THEW BOULTON, of Soho, in the County of Stafford, Esquire; for his Invention of improved Apparatus and Methods for raising Water, and other Fluids.

WITH TWO PLATES.

Dated Dec. 13, 1797.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said Matthew Boulton do hereby describe and ascertain the nature of the said invention, and the manner in which the same is to be performed, as follows; that is to say, for the more clear description of the said invention, it is proper to state its physical principle of action, as follows: First, when water moves or runs Vol. IX.

through a pipe, or close channel, or tube, if the end at which the water iffues be suddenly stopped, the water will (by its acquired motion, momentum, or impetus), act upon the sides or circumference of the pipe; which being supposed strong enough to resist that impetus, the water will issue, with violence or velocity, at any aperture which may exist in or near the shut-end of the pipe; and, if to that aperture an ascending pipe be joined, a portion of water will rise in it.

Secondly, if a pipe, open at both ends, with an afcending pipe, fuch as has been described, be moved along, through standing water, in the direction of its length, upon shutting the hinder part of the pipe, a portion of the water will rise in the ascending pipe, in the manner which has been stated in the former case, because the water is relatively in motion, in respect to the pipe.

Thirdly, if, in either of the cases recited, a pipe communicating with water at any lower level be joined to the main-pipe, at or near the end at which water enters into it, and if, when such water has acquired motion relatively to that pipe, (by the pipe being put in motion), the mouth or end at which the water enters is suddenly shut, the water, continuing its motion relatively to the pipe, will draw or suck up water from the lower level, through the ascending pipe, in order to fill up the vacuity occasioned by the water in the main pipe's

persevering in its previous motion. What has been faid respecting water, is also true in respect to other fluids.

The feveral cases above stated are resolvable into the general principle of the refistance which water and other fluids (and in general all bodies) make to a change of their state of rest, or motion, whether absolute or relative; and this principle has heretofore been applied to the raifing of water, only, in a comparatively small and weak degree, and in a defective manner. But the improved apparatus I am about to describe, in the several methods hereinafter specified, (excepting the several cases of the fixth method hereinaster mentioned.) continue their own action when once fet a going, unless some acident should stop or derange them; and are capable of raifing water in great quantities, and to great heights, except as to great heights in some few of the cases hereinaster specified and explained; and also differ, in other respects, from any thing which has been executed hitherto.

The nature of the faid improved invention confifts in ufing valves, of various conftructions, inflead of cocks, to open or flut the end or ends of a main pipe, as hereinafter described, and in the application of mechanism or contrivances to affist in opening and shutting the valves at proper times; whereby, and by the methods herein-

after specified, water is raised, independently of any power other than a current of water through the main pipe, and the mechanism aforesaid, except the fixth method as aforesaid; in which latter method some power is necessary to put the water in the main pipe in motion, (absolutely or relatively), as hereinaster described; and also in using proper materials for constructing the pipes, (as hereinaster mentioned,) in order to prevent the shock arising from the resistance aforesaid from causing the pipes to burst; which latter circumstance is essentially necessary to be attended to.

The manner in which the faid invention is to be performed, and the faid improved apparatus and methods carried into effect, is as follows, viz.

The first and most simple method is shewn in Fig. 1, (Plate VIII.) in which CC is the main pipe. DD the ascending pipe. A the valve of exit for the water to be raised. B the stop-valve; and E a weight, which, by the lever F, attached to the axis G of the stop-valve B, opens it at the proper time. The said apparatus acts in the following manner. The main pipe being situated or fixed in a current or stream of water, either produced by the natural current or declivity of a river or other stream, or (which is preferable) by penning up water by a dam, weir, or bank, and by inserting the end of the main pipe through the

faid dam, weir, or bank, fo as to obtain the greatest head or current of water the natural circumrances admit of, the stop-valve being opened to the position shewn in the figures, the water will run through the main pipe, until, by its action upon the stop-valve, in its reclined position, it raifes the weight, and fhuts the stop-valve, and the water, by its impetus or momentum, opens the exit-valve, and a portion of it rifes in the ascending pipe; after which the last mentioned valve shuts, the water in the main pipe recoils, the weight descends and opens the stop-valve, and the water in the main pipe regains its velocity. The like operations are repeated, and the water gradually rifes in the afcending pipe, until it reaches its fummit, and a quantity iffues thence every stroke; which quantity is more or less, according as the height to which it is raifed is less or greater.

This first method is not eligible where the water is to be raised to any considerable height; for the natural fragility, or imperfection, of even the best materials that can be procured for forming the pipes, causes a great danger of the rupture of the pipes, in this form of construction, unless the raising of the water be limited to the height of a few feet, or unless the pipes be made of an extraordinary thickness, disregarding expence.

This

This danger of bursting the pipes is to be regarded, in every case of applying this invention to practice.

The fecond method is shewn at Fig. 2, and is adapted to the raising of water to great heights as well as small. It differs from the former, in having an air-vessel or reservoir of air J, whereby the bursting of the pipes is prevented, or the danger thereof much diminished. Into this air-vessel the water from the main pipe enters through the exit-valve, and compresses the air in the vessel; which again, by its expansion or elasticity, acts upon the water, (the regress of which is prevented by the shutting of the exit-valve,) and the water rises through the ascending pipe, and, by repeated strokes, acquires the desired height.

The dimensions of the air-vessel, as well as its form and position, whether above or laterally affixed to the main pipe, are in great measure arbitrary; but its contents of air ought not to be much less than ten times the quantity of water to be raised through the ascending pipe each stroke, and if very much larger still the better, the principal boundary being expence.

The ftop-valve may be opened and thut, as has been described in the first method, by the mechanism shewn in the second figure, or by any of the mechanism hereinaster described as adapted to the opening of valves.

The third method is shewn at Figs. 3 and 4, annexed, and is applicable in cases where the vater to be raised is below the level of the main pipe, and is to be discharged at that level; which cases occur in the drainage of marshy lands, where the action of the current of water of an embanked river, or other stream or source of water on a higher level, can be employed; or this method can be applied in raising water out of the holds of ships, or other vessels, by the motion of the vessel through the water.

This is explained by Figs. 3 and 4; where C is the main pipe. A is the receiving-valve. B the ftop-valve, opening outwards. D the ascending or fucking pipe. J the air-veffel; and E the weight. The water in the main pipe having acquired a proper velocity, the stop-valve shuts: the water in the main pipe, continuing its motion for a time, draws air out of the air-veffel. Then, the momentum of the water in the main-pipe being expended, the receiving-valve shuts, and the stop-valve opens, the water regains its velocity, and the operation is repeated; and thus, in a few strokes, (the exhaustion encreasing,) the air-vessel fucks up water from below, by the afcending pipe; and this being continued, the latter pipe fills, by degrees, to the top; after which, at every fucceffive stroke, a portion of the water from below passes into the main pipe, and is carried off, with the upper water, to the place of delivery. The

The fourth method is shewn at Figs. 5 and 6; in which cases, the tide, or other alternating current, is employed as the power, and applied to the raifing of water, for the use of falt-works, or for other uses.

This is done in two ways, either by applying a stop-valve, air-veffel, &c. to each end of the main pipe, as in Fig. 5, to be used alternately, according as the tide fets in the one direction or the other; or by applying two main pipes to one air-vessel, as in Fig. 6, and to be used alternately, as aforefaid.

The fifth method is shewn in Figs. 7 and 8; in which the main pipe CCC is bent in form of a fyphon, to pass over some obstacle, such as a low hill, or eminence, not higher than thirty feet above the fource. In Fig. 7, the water raifed is fupposed to be delivered at the exit-valve A, on a level with the upper part of the bend of the fyphon, and the stop-valve B is placed at the entrance of the air-veffel.

The air-veffel is introduced, because, without it, the water in the leg C X would move only by ftarts, and, by being fuddenly ftopt in its motion, would act violently in thutting the stopvalve; but, by the intervention of the air-veffel, the water will run in CX nearly in a continued ftream, while it runs in an interrupted one in the leg C.C. It is necessary, in this form of con-

struction,

firuction, that the exit-valve should be placed under water, contained in a box or cistern, left ar should enter.

In the fyphon, Fig. 8, the stop-valve is fixed at the bottom or lower end of the delivering-leg CX; and, when that valve shuts, the water is discharged into the air-vessel J; whence it ascends, by the pipe D D, to the desired height.

The fyphon may be fet to work, either by pumping out the air, or by flutting both its ends and filling it with water, (as is usual in such cases,) when, the ends being opened, it will immediately set to work.

The fixth method relates to fuch applications of the above-mentioned general principle of refisflance, (or vis inertia,) as require the co-operation of fome independent or extraneous power, to put the water of the main pipe in motion, abfolute or relative,

Figs. 9, 10, 10 (a), 11, and 11 (a), (Plate IX.) flow fome applications of this method, in lieu of pumps, for raifing water.

Fig. 9, CC, is the main pipe, bent in a spiral form round the air-vessel J: it may either touch it, or be kept at a distance from it, and makes one or more revolutions round the said vessel. The whole of the main pipe is immersed in the external water to be raised; one end is open to it, and the other has a valve opening in-Vol. IX. wards;

wards; and, near this latter end, a communication is made, by a fide-pipe and exit-valve, with the air-veffel. The whole turns on a pivot K; and the afcending pipe D ferves as an axis, which is kept upright by a collar, in which it turns, at L. · Upon this axis is fixed a toothed wheel M, which is put in motion by another wheel N, turned by a winch, crank, or other contrivance. At the top or upper end of the afcending pipe, the water is discharged into a trough, which surrounds it, and conveys it to the place of its destination. This apparatus is made to raife water by a continued rotative motion, the open end moving first; for whenever, by that motion, the main pipe has attained a proper velocity, the stop-valve shuts, and water passes into the air-vessel, and the regress of the water is prevented by the shutting of the exit-valve; the stop-valve then opens, by means of a fpring: the apparatus continuing to revolve in the fame direction, more ftrokes are made, at intervals proportioned to the velocity with which it moves. The fpring should be adapted fo as not to prevent the relative motion of the water in the main pipe from shutting the stop-valve at proper intervals.

Figs. 10, and 10 (a), shew two constructions of this apparatus, in which the main pipe is made to vibrate round an axis, backwards and forwards;

the limits of the vibration or stroke being determined by a detent T firiking against a stiff spring In Fig. 10, the main pipe and the air-veffel are placed, not only out of the water to be raifed, but at the height to which the water is to be raifed, and the afcending pipe has its foot immerfed in that water: but this confruction should not be applied, in cases where the water is to be raised much more than twenty-feet. CC is the main pipe, bent in a circular form round the air-veffel J; at or near each end of which is a stopvalve B, opening outwards; and also a pipe or communication to the air-veffel, with a receiving valve A, opening towards the main pipe. D is the ascending pipe: at O is a valve, opening upwards, in order that when the ascending pipe is filled with water it may be retained. The perpendicular fection of the main pipe is drawn circular, but may be fquare, or any other convenient form; and a horizontal fection of it, with its ftop and receiving valves, is shewn in the plan and fide-view annexed.

Upon the ascending pipe or axis D, is fixed a double pulley P, about which are wound the ropes Q, R; by the pulling of which, alternately, the apparatus may be made to revolve in either direction. The main pipe and the ascending pipe being filled with water, by hand or otherwise, if the ropes Q, R, are pulled, alternately, X 2 with

with fufficient velocity, that is, if the apparatus makes about thirty vibrations in each direction in a minute, it will act well.

At Fig. 10 (a), the main pipe and air-veffel are placed near the bottom of the ascending pipe, so as that the main pipe may be wholly immersed in the water to be raised: stop-valves are placed at each end of the main pipe, as in the last figure, only they open inwards; and pipes or openings are made to communicate between each end of the main pipe and the air-vessel, having exit-valves opening towards the air-vessel. The same letters, in this figure, are put on parts that bear the same name as in Fig. 10, except that A, in this, is an exit-valve; and the apparatus may be wrought by the same means.

At Fig. 11, the main pipe CC is made in form of the fegment of a circle, of which the afcending pipes D, D, are radii; or it may be fimply a straight tube, pipe, or trough, forming the chord to such fegment. The whole is movable upon an axis U, at the centre of the fegment. S, S, are two stiff springs, which regulate the length of the stroke; which, if wrought by the power of men, acting at the circumference of the fegment, may be about three feet in each direction. At O O are valves, opening upwards, to retain the water in the ascending pipes when filled. The main pipe CC, and the ascending pipes D, D,

being

being filled with water, if the apparatus is pulled forcibly, first in one direction, and then in the other, it raises water from below; because, when it strikes either of the springs, the water in the main pipe, persisting in its motion, is partly thrown out, into the trough placed to receive it, and more water ascends through the ascending pipe, to supply the vacuity which would otherwise be formed.

In Fig. 11 (a), is represented an apparatus wherein the principal parts are in a position inverted, in comparison with those of Fig. 11; and the letters in this figure are placed on parts bearing the same name, except A, which in this case is an exit-valve. The whole of the main pipe should be immersed in the water to be raised; and then it may be made to raise water by such like means as are mentioned for the apparatus Fig. 11.

Every apparatus before described as belonging to the fixth method, admits of being put in motion by fire or steam-engines, or by water-wheels, or wind-mills, as well as by men, or horses, or other animals; and their sizes and dimensions are, in such cases, proportioned to their use, and to the nature of the power which works them.

The first, second, and third methods, above described, may be employed to raise water by

the motion of the waves of the fea, or of any large piece of water; in which case, the mouth or receiving end of the main pipe should be formed like a speaking-trumpet, and placed opposite to the direction in which the waves bear upon the shore at the place. The water of the waves will enter the main pipe, and rush through it until the stop-valve shuts; when the contained water will in part enter the air-vessel, as has been described, and the next wave will produce another stroke.

When this apparatus is to be actuated by the waves of water, or the open current of a river, eligible forms of the main pipe are shewn at X, in Figs. 1 and 2, in the annexed figures.

The dimensions of the several parts of the apparatus, in each of the several methods herein described, must vary according to the velocity and quantity of water passing through the main pipe, the height to which the water is required to be raised, and the quantity wanted to be raised in any given time. Proper materials for the main pipes and air-vessels are, cast iron, hammered iron, or copper, or brass, or other hard and strong metals, or mixtures of metals. For moderate heights and bores, wooden pipes would answer, and the better if strongly hooped. Strong earthen pipes, of moderate bores, would answer for small heights.

The valves and their mechanism are described as follows.

B, Fig. 1, is a common ftop-valve, moving upon an axle, or hinge, and affifted to open, at the proper time, by a weight attached to a lever fixed to its axis, at the proper angle; which confiruction has been delineated as applied to the feveral varieties of the apparatus herein before explained, though the following kinds are also applicable.

The weight must be adjusted by experiment. fo as to open the valves at the due times, according to circumstances; which may be done, either by fliding the weight nearer to, or further from, the centre of motion, or by encreasing or diminishing the weight itself. The inconvenience of this method is, that the weight being generally under water, it is troublesome to adjust it; therefore the mechanism in Fig. 12 is adapted to the stop-valve. The weight E is fitted upon a lever F, connected with a spindle J, to which the arm or lever G is also fixed; and that is connected, by the rod H, with the arm K, fixed to the valve. The rod H may be prolonged to any neceffary length, and the weight and its mechanism may be always placed above water, so as to be eafily come at, for adjustment. Valves of this kind are hinged, either upon their lower or upper edge, or upon one of the perpendicular fides, as a common door, according as conveniency requires,

quires, and the mechanism is connected accordingly.

Valve, which is circular, and, instead of being hinged upon one fide, is fixed upon a spindle in its centre, which slides in a socket or sockets, and, at the proper time, is opened by mechanism similar to the former here delineated, only, in place of the weight E, a spring is employed, which is also applicable in other cases.

In cases where the shock from shutting the stop-valve might derange the machine, some of the following valves are presented to those before described.

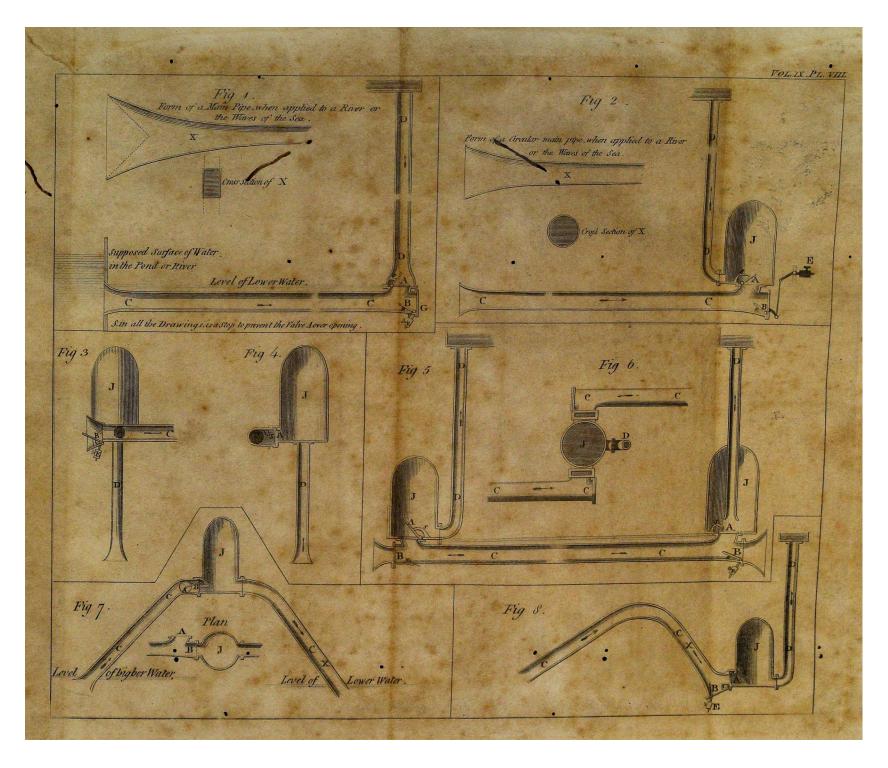

Fig. 14. is a ftop-valve which opens in two leaves, like the gates of a canal-lock: the leaves may flut upon one another in the middle, or may shut upon an upright bar placed there, as represented in the horizontal section and frontview; and they are opened by the same kind of mechanism as hath been described before, only there must be two connecting rods, one to each leaf of the valve. The aperture for this valve is of a rectangular figure. A valve in two leaves may also be hinged in the middle of the opening, but would too much obstruct the water-way. When the main pipe is of a large diameter, (two feet or upwards,) the stop-valve may be made in three, four, or more leaves, connected together by mechanism, as in Fig. 15, where an iron

grating or frame is represented for supporting the valves; and mechanism, of the same kind as that described for the more simple valves, is applied to open them.

At Fig. 16. is delineated a valve turning upon an axis, like a common fire-flove chimneydamper: the axis does not pass through its centre, but divides it into two unequal fegments. The valve is not opened fo far as to ftand in the line of the current of water, but stands, when opened; inclined to that current; fo that the larger fegment being placed towards the stream, the latter may, by its action, shut it at the proper time, and it is opened by mechanism similar to that described: any other species of valve. which is capable of being thut by the current and opened by mechanism, or opened and flut by mechanism folely, at the proper times, will answer this purpose. When the stop-valve is required to open fo completely that the current of water in the main pipe cannot act upon it fo as to thut it, a finall stream of water is led from the head which fupplies the main pipe, or from forne other fource, in a pipe or trough, which is furnished with a cock, shuttle, or other contrivance. to regulate the quantity. This pipe or trough pours its water into the bucket E, of the contrivance Fig. 17, which causes the bucket to preponderate, and, by means of the lever fixed to its axle, and the rod attached to it, thuts the Vol. IX.

stop-valve: the bucket then empties its water, and the weight F, as foon as the recoil of the water in the main pipe takes place, prepondel rating in its turn, opens the valve, and reftgres the bucket to its place. By opening the cocks more or less, and by the capacity of the buckets, in proportion to the weight F, the number of strokes to be made in any given time is regulated. Excepting the last mentioned stop-valve, Fig. 17, all the stop-valves before described, should be prevented from opening to such a degree that the action of the current of water could not shut them. This may be done by some fixed refistance behind the valves, as shewn at Fig. 1, and feveral other figures, or by any other convenient means.

When this invention is made use of in an open river, which does not admit of having its water penned up by a weir or dam head, the main pipe ought to be laid so as to be covered by the low waters of the river; and it ought to be parallel to the surface of the river, so as to have the greatest possible declivity that can be obtained in the length of the main pipe: its mouth or receiving end should be shaped like that of a trumpet, or bell. In all cases whatsoever, the valves ought to be compleatly under water, otherwise some air will enter at every stroke, and derange the operations of the apparatus. In witness whereof, &c.

XX. Specification of the Patent granted to Mr. JOSEPH BARTON, of the Parish of St. Botolph, Bishopsgate, in the City of London, Chemist; for an improved Method of preparing Indigo for the Purpose of dying Wool, Silk, Linen, Cotton, and other Articles, and Goods made and manufastured of the same, and for giving the Blue Shades to all Kinds of Linens, Woollens, Papers, and other Substances, in a more perfect Manner than hitherto discovered.

Dated March 25, 1797.

TO all to whom these presents shall come, &c. Now know YE, that in compliance with the said proviso, I the said Joseph Barton do hereby declare, that my said invention is described in manner following; that is to say, in consequence of the infinite variety in the quality of indigo, it is wholly impossible to state the quantity of the different materials necessary in the processes of the preparation; these must, in a great measure, depend on the quantity of colouring principle Y 2 contained

contained in the indigo acted upon. The indigo being ground as fine as possible, and its quality, as to quantum and colour, afcertained, by its perfect folution in acid or alkaline folvents, a fufficient quantity of tin, iron, zinc, or alum, or all or any of them combined, to give a fixing bafe to the colouring matter of the indigo, is added; carefully neutralizing any fuperabundance of folvents used in diffolving the indigo and metals; which would otherwife injure the durability and the beauty of the colour, and render it more difficult of combination with other colours and fubstances used in dying, and preparing goods for that purpose; for the powerful acids, or alkalies, necessary to dissolve indigo, destroy many, and injure nearly all, dying drugs or materials. In witness whereof, &c.

XXI. Specification of the Patent granted to Mr. ROBERT JOHNSTON*, of Greek-fireet, Soho; for his Invention of a Medicine which be calls Improved Effence of Mustard,

Dated March 30, 1798.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said Robert Johnston do hereby declare, that my said invention is described in manner following; that is to say, take the whole plant and root of the white and brown mustard, and the white and brown mustard-seed, any quantity; and, with a sufficient quantity of water, distil therefrom the effential oil. Put this essential oil, with an equal quantity of the essential oil of juniper and the purest alkohol, into a retort; and, with as gentle a heat as possible, draw it over, and keep it very closely stopped. Digest cloves in fresh quantities of pure alkohol, so long as they afford any slavour: silter it, put it into a cucurbit, and dis-

^{*} This name is, by miftake, printed Johnson, in our last List of Patents, page 143.

166 Pat at for improved Essence of Mustard.

til off the spirit, till it begins to thicken; to this refiduum add a proper quantity of distilled water, and it will precipitate; divide this precipitate into flat cakes, and dry it with a gentle heat. Digeft gum-guaiacum in the purest alkohol; filter it; distil off a part of the spirit till it begins to thicken; precipitate with water, and dry it in the fame manner. Take of the above preparation of cloves 1 lb. 3 oz. the preparation of guaiacum 2 lb. 7 oz. balsam of Peru 1 lb. 5 oz. balsam of Tolu 1 lb. 9 oz.; intimately mix the whole together, and stiffen it so as to form a hard mass with Ruffia caftor, powdered; with which caftor three drachms of the above effence of mustard is to be mixed: to each pound of this mass, fix drachms of genuine Kermes mineral is to be added, and then formed into pills. Take brown mustard-seed 36 lb. pour thereon 40 gallons of effential oil of turpentine, boiling-hot: let it stand till cold, and then put it all into the still, with a fufficient quantity of water, and draw 39 gallons: to this add 2 lb. of animal-oil, or oil of hartfhorn, (rectified by repeated diffillations in a retort, till divefted both of colour and fmell,) 50 lb. of camphor, 4 lb. of effential oil of rofemary, 4 oz. of effential oil of cloves, 1 lb. of English oil of lavender, and fix drachms of the above effence of mustard. In witness whereof, &c.

XXII. Specification of the Patent granted to Mr. JAMES BURN, of Alnwick, in the County of Northumberland, Hatter; for his Invention of a Composition for the making of Hats.

Dated March 2, 1792.

O all to whom these presents shall come, &c. Now know yE, that I the faid James Burn, in compliance with the faid proviso, do hereby defcribe and afcertain the nature of my faid invention, and declare, that my new composition for the making of hats confifts of the following particulars, in the proportions following; that is to fay, three ounces and an half of mole fur, two ounces and an half of rabbits wool, one ounce of beaver, and a quarter of an ounce of Aleppo wool; and, in order to fubdue the obstinate nature of the mole fur, fo that it may incorporate with other furs usually made into hats, I use a little aqua regia; but, as that process destroys the elastic quality of the fur, I correct it by a little fweet or Florence oil, which sheaths the pungent points of the aqua regia. With this preparation, I make hats of the finest quality. In witness whereof, &c.

XXIII.

XXIII. On the Usefulness of washing and rubbing the Stems of Trees, to promote their annual Increase. By Robert Marsham, of Stratton, in the County of Norfolk, Esquire, F. R. S.

From the Philosophical Transactions of the Royal Society of London.

I HAD for feveral years intended to put in practice the celebrated Dr. Hales's advice of washing, with that of Mr. Evelyn of rubbing, the stem of a tree, in order to increase its growth; but other avocations prevented me till the last fpring, when, as foon as the buds began to fwell, I washed my tree (a beech) round, from the ground to the beginning of the head, viz. between thirteen and fourteen feet in height. This was first done with water and a stiff shoe brush, until the tree was quite cleared of the moss and dirt, then I only washed it with a coarse flannel. I repeated the washing three, four, or five times a week, during all the dry time of the fpring, and the forepart of the fummer; but after the rains were frequent 1 very feldom washed. The unwashed tree, whose growth I proposed to compare with

it, was, (at five feet from the ground,) before the last year's increase, three feet, seven inches nine tenths; and in the autumn, after the year's growth was compleated, three feet, nine inches one tenth; viz. increase one inch two tenths. The washed tree was last spring three feet, seven inches two tenths, and in the autumn it was three feet, nine inches feven tenths; viz. increase two inches five tenths; that is, one tenth of an inch more than double the increase of the unwashed tree. As the difference was fo great, and as fome unknown accident might have injured the growth of the unwashed tree, I added the year's increase of five other beeches of the fame age, (viz. all that I had measured,) and found the aggregate increase of the fix unwashed beeches to be nine inches three tenths, which, divided by fix, gives one inch five tenths and a half, for the growth of each tree; fo that the gain by washing is nine tenths and a half. To make the experiment fairly, I fixed on two of my largest beeches, fown in 1741, and transplanted into a grove in 1749. The washed tree had been, from the first year, the largest plant, till the year 1767, when its rival became and continued the largest plant, until I began to wash the other; therefore I fixed on the less thriving tree as the fairest trial. The trees were nearly of the fame height and shape, spreading a circle of about fifty feet diameter. I Vol. IX. think

think it necessary to mention these circumstances; for I know, by experience, that a fhort and fpreading tree, having ample room, will increase twice or three times, or perhaps four times, as much as a tall fmall-headed tree, of the fame age, that stands near other trees. Thus, my washed beech increased about fix times as much as Mr. Drake's beautiful beech as Shardeloes, though that tree feemed in good health, when I faw it in 1759 and 1766. But it increased only two inches nine tenths in those seven years; which may perhaps be owing to its vast height, being feventy-four feet and a half to the boughs, (as the late knight of the shire for Suffolk, Sir John Rous, told me Mr. Drake had informed him,) only fix feet and four inches round, and having a small head, and little room to fpread.

Possfcript *. In my former paper I shewed how much a beech increased, upon its stem being cleaned and washed; and in this I shall shew, that the benefit of cleaning the stem continues several years; for the beech which I washed in 1775, has increased, in the five years since the washing, eight inches and six tenths, or above an inch and seven tenths yearly; and the aggregate

^{*} The Postscript was written some years after the preceding letter,

of nine unwashed beeches, of the same age, does not amount to one inch and three tenths yearly, to each tree. In 1776, I washed another beech, (of the same age, viz. feed in 1741,) and the increase in four years, fince the washing, is nine inches and two tenths, or two inches and three tenths yearly; whereas the aggregate of nine unwashed beeches amounted but to one inch three tenths and a half. In 1776, I washed an oak which I planted in 1720, which has increased, in the four years fince washing, feven inches and two tenths; and the aggregate of three oaks, planted the fame year, (viz. all I meafured,) amounted to but one inch yearly to each tree. In 1779, I washed another beech, of the same age, and the increase in 1780 was three inches; when the aggregate of fifteen unwashed beeches was not full fifteen inches and fix tenths, or not one inch and half a tenth to each tree; yet most of thefe trees grow on better land than that which was washed. But I apprehend the whole of the extraordinary increase, in the two last experiments, should not be attributed to washing; for, in the autumn of 1778, I had greafy pond-mud fpread round some favourite trees, as far as I supposed their roots extended; and although fome trees did not feem to have received any benefit from the mud, yet others did; that is, an oak increased half an inch, and a beech three tenths, above 7,2

their ordinary growth. Now, though the beech gained but three tenths, yet perhaps that may not be enough to allow for the mud; for the fummer of 1779 was the most ungenial to the growth of trees of any fince I have meafured them, fome not gaining half their ordinary growth; and the aggregate increase of all the unwashed and unmudded trees that I measured (ninety-three in number, of various kinds) was, in 1779, but fix feet, five inches and feven tenths, or feventy-feven inches and feven tenths; which gives but eight tenths and about one third to each tree; whereas, in 1778 (a very dry fummer in Norfolk) they increased seven feet and nine tenths, or near eighty-five inches, which gives above nine tenths to each tree; and, in the fummer of 1788, which was also very dry, the aggregate increase was above half an inch more than in 1778. But the greatest increase of these three years is low, as there are but twenty of the ninety-three trees that were not planted by me and greater increase is reasonably expected in young than in old trees; yet I have an oak, two hundred years old in 1780*, which is fixteen feet and five inches in circumference, or one hundred

^{*} I cannot mistake in the age of this oak, as I have the deed between my ancestor Robert Marsham and the copyhold tenants of his manor of Stratton, dated May 20, 1580, upon his then inclosing some of his waste, and the abuttal is clear.

and ninety-feven inches in two hundred years: · but this oak cannot properly be called old. The annual increase of very old trees is hardly meafurable with a ftring, as the flightest change of the air will affect the sting more than a year's growth. The largest trees that I have measured are fo far from me, that I have had no opportunity of measuring them a second time, except the oak near the Honourable Mr. Legge's lodge, in Holt Forest, which does not appear to be hollow. In 1759, I found it was, at feven feet, (for a large fwelling rendered it unfair to meafure it at five or fix feet,) a trifle above thirty-four feet in circumference; and, in 1778, I found it had not increafed above half an inch in nineteen years. This more entire remain of longevity merits some regard from the lovers of trees, as well as the hollow oak at Cowthorp, in Yorkshire, which Dr. Hunter gives an account of in his edition of Evelyn's Silva, and calls it forty-eight feet round, three feet. I did not measure it so low; but, in 1768, I found it, at four feet, forty feet and fix inches; at five feet, thirty-fix feet and fix inches; and at fix feet, thirty-two feet and one inch. Now, although this oak is larger near the earth than that in Hampshire, yet it diminishes much more suddenly in girt, viz. eight feet and five inches, in two feet of height. (I reckon by my own measures, as I took pains to be exact.) Suppose

Suppose the diminution continues about this rate, at seven feet (I did not measure it so high) it will be about twenty-eight feet in circumference: and the bottom sourteen feet contain six hundred and eighty-six seet round or buyers measure, or seventeen ton and six seet. Fourteen feet length of the Hampshire oak is one thousand and seven seet, or twenty-sive ton and seven seet; that is, three hundred and twenty-one seet more than the Yorkshire oak, though that is supposed, by many people, to be the greatest oak in England.

I am unwilling to conclude this account of washing the stems of trees, without observing, that all the ingredients of vegetation united, which are received from the roots, stem, branches, and leaves, of a mosfy and dirty tree, do not produce half the increase that another gains, whose stem is clean to the head only, and that not ten feet in height. Is it not clear, that this greater thare of nourithment cannot come from rain? Fethe dirty frem will retain the moisture longer than when clean: and the nourishment drawn from the roots, and imbibed by the branches and leaves, must be the same to both trees. Then must not the great share of vegetative ingredients be conveyed in dew? May not the moss and dirt absorb the finest parts of the dew? And may they not ast as a kind of screen, and deprive the

tree of that share of fun and air which it requires? To develop this mysterious operation of nature, would be an honour to the most ingenious, and the plain fact may afford pleasure to the owners of young trees; for, if their growth may be increafed by cleaning their ftems once in five or fix years, (perhaps they will not require it fo often,) and if the increase is but half an inch yearly above the ordinary growth, it will greatly overpay the trouble, befides the pleasure of seeing the tree more flourishing. Although the extra increase of my first washed beech was but four tenths of an inch, the fecond was nine tenths and a half, and the third near two inches; fo that the aggregate increase is above one inch and one tenth yearly; and the increase of the oak is eight tenths. But, calling it only half an inch, fix years will produce above five cubic feet of timber, as the oak is eight feet round, and above twenty feet long, and fixpence will pay for the washing; consequently, there remain nine shilimgs and fixpence clear gain, in fix years.

XXIV. Farther Observations respecting the best Manner of planting Potatoes. By Mr. Joseph Wimpey, of Braton-Clovelly, near Okehampton, Davon.

From the Letters and Papers of the Bath and West-of-England Society for the Encouragement of Agriculture, &c.

I FORMERLY gave an account of an experiment made to discover whether whole potatoes or cuttings are to be preferred in planting *.

From that account it clearly appeared, that the advantage lay greatly on the fide of cuttings. But as, from long experience, I know conclusions drawn from fingle experiments cannot be fafely depended on, and as the refult of that experiment differed so widely from an account given by a very respectable correspondent of the So-

^{*} For Mr. Wimpey's former observations on planting potatoes, see our eighth volume, page 49.

eiety, whose accuracy is well known, and of whose probity and veracity I have the highest opinion, I resolved to repeat my former experiment as exactly as possible, by way of establishing a fact so interesting to the public, if found just, or of retracting an error, if it should appear to be one.

In the fpring of 1791, I prepared about three acres of ground, and in April planted it with potatoes. A certain quantity of the largest and finest were selected, one half of which were planted whole, the other cut into pieces of a moderate fize. An exact account of each was kept at taking up, when it appeared that the produce per acre was much the fame as in the former experiment; but, as the cut potatoes planted nearly four times the ground that the whole fets did, the advantage lay, in the same proportion, on the fide of planting with cut potatoes; therefore I think there cannot be the least doubt that the preference is to be given to cuttings, as the fuccess of the two experiments so nearly coincides.

I have been used for some years to surnish my neighbours with potatoes for planting. The last season, one of them desired I would let him have them all small. He said he had planted small ones several years, that he sound them equally Vol. IX.

178 Farther Observations on planting Potatoes.

productive with the largest, and saved much trouble in cutting. Others (who carried their œconomy much farther) preferred the largeft; they, it feems, used to pare them, to eat the fleshy part, and to plant the rinds only. Upon enquiry, I found this was not an unufual practice among the cottagers; and, I have been credibly informed that they get as large crops, and as good potatoes, in that method of planting as in any other whatever. If this be a fact, it feems to appear, that the fleshy part of the bulb is of no use in supplying nourishment to the young fruit, after the fibrous roots have put forth, and laid hold of the ground. Perhaps an experiment of this fort may be thought worth making.

XXV. Experiments and Observations on Fermentation, and the Distillation of Ardent Spirit. By Mr. Joseph Collier.

WITH A PLATE.

From the Memoirs of the Literary and Philosophical Society of Manchester.

WE may lay it down as an incontestible axiom, fays Lavoisier, that in all the operations of art or nature nothing is created. An equal quantity of matter exists, both before and after the experiment: the quality and quantity of the elements remain precisely the same: and nothing takes place, beyond changes and modifications in the combinations of those elements. Upon this principle, the whole art of performing chemical experiments depends. We must always suppose an exact equality between the elements of the body examined, and those of the products of its analysis *.

* Elements of Chemistry.
A a 2

The fubject of fermentation, but more particularly the fermenting infusion of malt, has been very little attended to as an object of chemical enquiry. Diodorus Siculus, Herodotus, and Tacitus, mention a method of making wine from malt; yet the modern world had made very little progress, either in improving the process, or afcertaining its products; until Dr. Priestley and the Duke of Chaulnes made their interesting experiments, on the carbonic acid gas difengaged during the operation of fermentation. Soon after thefe important discoveries were communicated to the public, the accurate philosopher whom I first quoted, inftituted a fet of most valuable experiments on this subject; and from their results established a firm base for farther enquiry. Before this period, all was undefined, and the chemift had nothing to direct his attention but fcattered facts, many of which rather tended to confound than properly to conduct his investigation.

The distillation of ardent spirit has met a similar fate to that of fermentation. The Egyptians, at a very early period, discovered the art of drawing spirit from wine. Modern chemists have left it in the rude hands of the ill-informed, and accident has been the chief contributor to its improvement. It is true, that some of the proof spirits of commerce are pure and good; but this arises more from the nature of the wines from which

which they are drawn, than from the superior skill of the distiller. The sugar-cane and the grape are eafily attenuated by fermentation, and contain less fœtid oil than malt; neither are they so liable to contract an empyreuma in the still. I was induced to begin this enquiry from a firm perfuafion, that it was possible, by means of known chemical agents, to produce malt spirit equally pure with that which is obtained from any other modification of faccharine matter; and most of the following facts are confined to maltliquor. Many other particulars have occurred, in the course of my experiments, which I thought worthy of notice, and which I shall transcribe from my notes; but I shall first make a few obfervations on fermentation in general.

Fermentation is an intestine motion in the solution of faccharine matter, whereby a new arrangement of its constituent elements take place, and alcohol is produced, without the intervention of any other agent, of any denomination whatever.

From the above definition it will appear, that I mean to exclude all operations from the denomination of fermentation, excepting that in which wine is produced, and, confequently, alcohol. Bellini fays, that all things are full of ferments; and Van Helmont affirms, that fermentation is the fole cause of almost every transmutation.

tion. But the excellent Boerhaave was aware of the confusion which was likely to arise from general terms, and, therefore, limited the word fermentation to three distinct operations: the formation of alcohol, the making of vinegar; and the production of ammoniac; fince which, a vinous, an acetous, and a putrid fermentation have been generally acknowledged: the second as a consequence of the first; and the third as a consequence of the two former.

My prefent object is neither to enter fully into the investigation of acetous acid, nor of the cause of putrefaction; but I shall make a few remarks upon each.

To produce vinegar, (which is chiefly obtained from fermented liquor,) the presence of an acid is necessary, such as the tartareous acidula; but it may be obtained by other vegetable acids, as well as from gums and amylaceous secula dissolved in water. A heat of from seventy to ninety degrees of Fahrenheit's thermometer is also necessary to the production of vinegar; and sermented liquors will become acid, under this temperature, by the solution of the tartar only; yet a persect vinegar cannot be formed in a close vessel. A free access of vital air is absolutely necessary to the production of acetous acid, but is highly injurious to the spirituous fermentation: add to this, that insipid mucilages or gums dissolved in water, be-

come acid, without having been discernibly spirituous. Why then should the making of vinegar be called fermentation?

The production of ammoniac, which is called the putrid fermentation, arises from the texture of the folids being destroyed, and the nature of the fluids being altered; and it is a well-known fact, that many vegetable and other fubftances never undergo any fenfible vinous fermentation, or are formed into vinegar, previous to putrefaction. In some of my experiments on the fermenting infusion of malt, I have observed a beginning putrefaction, without any previous acidity; which I attribute to an entire completion of the spirituous fermentation, whilft the air was excluded, and the heat never fufficient to diffolve the tartar. It has been before observed, that a heat of from feventy to ninety is required to form the acetous acid, but putrefaction will take place in a temperature of forty-five. The putrefaction of vegetables volitalizes and reduces them to an earthy state; but, to mark the phænomena of vegetable putrefaction, and to diftinguish it from the putrefaction of animal matter, will form the subject of another effay; in which I shall endeavour to prove, that the production of nitre, and the formation of vegetable mould, might with equal propriety be called fermentation, as the production of ammoniac; both being products of putrefaction.

Fermentation

Fermentation must, therefore, be either confidered as a general term, and supposed, according to the opinion of Van Helmont, to be the sole cause of almost every transmutation; or it must be limited to express some definite process, by which one or more specific products are obtained. In the latter case, the most common application will certainly be deemed the most proper, viz. the production of alcohol, by an intestine motion in the solution of faccharine matter, without the intervention of any other agent whatever.

Some chemists are of opinion, that insipid or gummy mucilages, barley, &c. pass by a fort of fermentation into saccharine matter; but of this I shall speak more at large, when treating on the subject of malting.

No other but faccharine matter is susceptible of fermentation, and it is necessary to observe a proper proportion between the density of the liquor and the quantity of yest; for, although artificial ferment is not absolutely necessary to produce fermentation, yet it has a tendency (as is well known) to accelerate its progress.

The heat of the liquor must also be regulated according to the density; as a greater or smaller degree of heat is excited during fermentation, according to the quantity of fermentable matter which the liquor contains.

The phænomena which accompany fermentation, together with many other interesting particulars, may be found in an ingenious essay on the subject, by Mr. Thomas Henry *. I shall, therefore, proceed to a description of the instrument by which I regulated the gravity of my worts.

The scale of my faccharometer corresponds to that of Blake's, but the form is materially different. It is so constructed, that a plate above the ball is fufficiently large to contain a scale of the intermediate gravities, including the strongest and weakest worts with which the experiments were made. It begins with o, and proceeds by equal divisions to 80°; a denfity which cannot be properly attenuated, without repeated fermentations with large quantities of yest. In the middle of the plate stands a thermometer, graduated from o to 100°; the use of which will be explained by and by. The divisions in the scale were made on a supposition that malt was worth about two pounds the quarter; whereby every varying degree that should be found in two worts, where equal quantities had been drawn from two different kinds of malt, would indicate a difference in value, of fo many fixpences.

VOL. IX.

^{*} Mr. Henry's Effay is printed in our feventh volume, page 46.

The faccharometer ought to be accompanied by an affay-veffel, which is nothing more than a cylindrical jar of tin.

When it is to be used, fill the affay-jar with wort, and reduce it to fixty degrees of heat. Then leave the instrument at full liberty, in the jar of wort, and it will rest at the proper degree of density, which will be found upon the scale *.

If the liquor be not cooled to fixty degrees, one degree of denfity should be allowed for every additional five degrees of heat.

When the above regulations are attended to, the following will be found to be nearly the denfities or gravities of some of the most celebrated malt liquors, both before and after fermentation.

Porter has fixty-fix degrees of denfity before fermentation; but is reduced, by a proper fermentation, to twenty-fix degrees of denfity.

Ringwood ale, seventy-four degrees before fermentation; but is reduced to thirty after.

* I believe this faccharometer will be found pretty acquarate; yet, "there are other principles in fluids befides their gravity, by which they refift the admission of a descending body, and the first of these is that of attraction: which, operating powerfully on bodies composed of heterogeneous particles, must have considerable influence in such a fluid as wort. A tendency to coagulate in the higher temperatures, and an approach to congelation in the lower, are certainly co-operating principles in all gelatinous liquors." See the Appendix to Richardson's Statical Estimates.

Dorchester

Dorchefter ale, eighty-four before, and forty-five after.

Table beer has forty degrees of denfity before fermentation, but only twenty-two after.

From the foregoing observations, the use of the saccharometer is sufficiently manifest: it not only serves as a guide to the quantity of liquor to be drawn from malts of different qualities, but also to determine whether those liquors are properly attenuated by fermentation.

The first part of the experiments is arranged in the following order.

I. On the production of artificial ferments, with a view to afcertain their relative values *.

II. Whe-

* Boerhaave arranges, what he calls principal ferments, in the following order. 1. All those things which, of their own nature, are greatly disposed to ferment, so as immediately to begin this operation without any other ferment: fuch as the juices of ripe fummer-fruits, which are fo ftrongly disposed to ferment, as fcarcely to be kept quiet without the help of things that prevent fermentation. So likewife a paste made of flour and water, and laid in a warm place, cannot then be hindered from fermenting. Hence, we need not be folicitous about a first ferment, because nature spontaneously affords it every where. 2. The recent flowers thrown to the top of beer, in the act of fermentation; for, if this rarified frothy matter be mixed with other fermentable liquors, it greatly promotes their fermentation. 3. The fame matter, now become heavier, and funk to the bottom, provided it be not B b 2

II. Whether the fermentation ought to be carried on in open or close vessels.

III. The effects of different factitious airs on fermenting liquors.

- I. From a confiderable number of experiments on artificial ferments, I shall select the fix following.
 - 1. I took four ounces of wheat-flour, and a pint of water. The water, when mixed with the flour,

too stale, still retains the same virtue, though in a less degree than the former. In this flate it is called lees; and, being by motion mixed with its own wine, it often occasions a new fermentation, and will excite it in other subjects. 4. Cassia. honey, manna, fugar, and the like inspissated juices. 5. Paste of flour fermented, or baker's leaven: for, though meal may be preserved for years, fresh and sweet, in a dry place. and kept from infects; yet, if wrought with water into a foft, fweet, and close paste, and lightly covered, in a warm place, it will, in an hour's time, begin to heave, fwell, rarify, become all over full of cavities, change its fmell, tafte. and tenacity, prove acid both to the tafte and fmell, and thus become that proper ferment, which gave the original name of this whole operation; because, when thus prepared, if a part of it be mixed with other fresh paste, not yet fermented, it now causes it to ferment much sooner and stronger. 6. The remains of former fermenting matters, flicking to the fides of casks, every way penetrated by the subtilty of the wines they before contained, become extremely apt for raifing quick and violent fermentation in fresh liquors put into them. 7. The white of eggs beat up to a froth, &c. See the Practice of Chemistry, p. 108.

was of about eighty degrees of heat, and the mixture was placed in a temperature varying from fixty-five to feventy-five, for five days.

- 2. To a mixture fimilar to the above, and of the fame degree of heat, I added an ounce of muriat of foda, (common falt,) which was also left in a temperature varying from fixty-five to seventy-five, for five days.
- 3. The same proportions of water and flour were mixed as in the first and second experiments, and put into Nooth's apparatus, and subjected (as in Mr. Henry's Experiments) to the action of the carbonic acid gas, for five days.
- 4. A quart of strong infusion of malt * was placed in the same temperature, for an equal length of time.

5. To

* The method proposed by Mr. Mason, (which is inserted in the Transactions of the Society for the Encouragement of Arts, Manufactures, and Commerce,) is as follows:

Procure three veffels, of different fizes or apertures; one capable of holding two quarts, the other three or four, and the third five or fix. Boil a quarter of a peck of malt, for about eight or ten minutes, in three pints of water; and when a quart is poured off from the grains, let it ftand in a cool place, till not quite cold, but retaining the degree of heat which the brewers usually find to be proper, when they begin to work the liquor. Then remove the veffel into fome fituation near the fire, where Fahrenheit's thermometer flands between feventy and eighty, and there let it remain till the

- 5. To another quart of malt-liquor, were added three ounces of a strong infusion of hops, and treated as before.
- 6. An equal quantity of the infusion of malt was put into the middle part of Nooth's apparatus, and subjected (like the flour and water) to the action of the carbonic acid gas, for five days.

All the foregoing compounds began to ferment about the same time, (four days after the mixture was made;) but, in order more fully to afcertain their real value, I took fix veffels, into each of which I put three gallons of wort, of forty-five degrees of denfity. One of the above ferments was put into each veffel of liquor, and they were all placed together, in a temperature of fifty-one degrees, for eight days; at the end of which time, each parcel was feparately diffilled; but the quantity of spirit obtained was so nearly similar in all, that I have kept no account of their respective products. It must, however, be observed, that the quantity of spirit formed was much less than might have been produced by the affiftance of a little yest. At the same time it is obvious, that

fermentation begins, which will be in about thirty hours; then add two quarts more of a like decoction of malt, when cool, and flir it well in the larger-fized vessel; then proceed as before; after which, add an equal quantity more, and mix all in the largest vessel, and it will produce yest enough for a brewing of forty gallons."

fermentation may be effected, by fubjecting folutions of faccharine matter to a proper temperature, without the addition of an artificial ferment. This is a farther proof of Dr. Pennington's opinion, that worts would ferment without yest; though a much greater length of time is necesfary, and after all the operation is not so persect.

With respect to the doctor's opinion on the raifing of bread, I think it is by no means conclufive. He takes a quantity of dough, and fubjects it to the action of yest, for three quarters of an hour, and then commits it to distillation: he obtains some water, but no spirit; from which he concludes, that bread is not raifed by fermentation. Had the doctor faid that a complete fermentation was not necessary to raise bread, I should have had no objection to his hypothesis. An operation is certainly begun, which in nine or fixteen hours, according to his own experiments, forms a fpirit. This observation was suggested on my first reading Dr. Pennington's Inaugural Differtation; but in order more fully to fatisfy myself, I took a gallon of wort, to which I added, at a proper temperature, two ounces of yest. The mixture was made in a glass jar, and I observed all the figns of a beginning fermentation, fuch as a motion excited in the liquor, the bulk of which was increased, and rendered turbid by the appearance of opaque filaments, together with an increase

increase of heat. After it had stood three quarters of an hour, I distilled it, but not a drop of spirit came over. It may be urged, that this is only a negative fact; but, when we observe that a change is effected in the dough, similar to that in the fermenting malt-liquor, in an equal length of time; when we see the products of each turn out exactly alike; and when we consider that dough of itself ferments in a few days, without the addition of yest, we have, at least, presumptive evidence, that the raising of bread is a beginning of fermentation.

I have made fome additional experiments, to produce artificial ferments from molasses, sugar, honey, and the expressed juice of ripe fruits; but as I found them all much inferior to the flowers of wine, or common yest, my subsequent experiments were all assisted by the latter.

When I mention the quantity of yest used, I mean to be understood, one part of dry yest *, (dried upon canvas,) and seven parts of water.

TO BE CONCLUDED IN OUR NEXT.

XXVI. Conclusion of M. Ribicourt's Observations on the Composition of Writing Ink.

(From Page 142.)

On the different Liquors which have commonly been made use of in making-Ink.

WATER, white-wine, beer, and vinegar, are the liquors which have been usually employed in making ink; every author having his own particular opinion refpecting them, and recommending that which he thinks preferable, to the exclusion of the others: some use any of them indifferently. This is, however, by no means a matter of indifference: that liquor which can best excract the colouring matter, and diffolve the faline fubstances and the gum, and which joins to these properties that of having no immediate action upon the colour of the ingredients, must certainly be the most likely to produce an ink of the blackeft colour, and one which will preferve that colour for the longest time. Now, I shall prefently shew, that the other fluids above men-VOL. IX. · Cc

tioned, far from surpassing water in these respects, do not even equal it.

In the first place, those inks which are made with white-wine, beer, or vinegar, are not more black than those which are made with water; and, instead of their keeping good a longer time, I have ascertained, by many experiments, that the writings of ink made with vinegar grow rusty and yellow, while those of ink made with water preserve their original blackness.

It might indeed be supposed, that white-wine, and, still more, that vinegar, would be preferable to water, because their acid would seize upon the oxide of iron, as it quits the fulphuric acid; probably it was on this account that they were prefered to water; but I have shewn, that the colouring matter which envelops the iron, renders it incapable of being acted upon by acids. I have likewise shewn, that the oxide of iron acquired a black colour, and formed ink, not as being diffolved by an acid; but, on the contrary, as being precipitated from its folution. It is also an established fact, that a folution of iron in the acid of vinegar, produces a very pale ink, the colour of which foon fades and disappears; in short, an ink of very little value.

I may add, that to put vinegar into ink, is to increase the quantity of free acid; and it is certainly to the action of the free acid in ink, affifted

affifted by that of the air, that the alteration which takes place in the colour of writings is to be attributed. For it cannot be doubted, that the acid is concentrated by the drying of the ink, and that its action upon the black precipitate (which it finds in a state the most favourable to its decoloration) is more powerful than when, being itself very much diluted, and confequently very weak, it meets the precipitate in a larger mass, and defended from the contact of the air; consequently, in a state less fit to be acted upon. It is, therefore, not to be wondered at, that ink which is prepared with vinegar should appear as black, when used, as that which is prepared with water; and yet that the writing which is made with the first should grow yellow, while writing made with the other preserves its black colour unchanged.

I have not observed that beer contributes to the goodness of ink; on the contrary, I have remarked, that it renders it too thick, and makes it more liable to grow mouldy than when made with other liquors.

Water is, therefore, the most proper liquor to be employed in the composition of ink; and (whatever may have been said to the contrary) every kind of water is sit for the purpose; the hardest water appears to be equally good as rain water, or even as distilled water.

G C 2

On the Proportions of the Ingredients which enter into the Composition of Ink; and, first, of those of Galls and Sulphate of Iron.

There is a great difference amongst authors, with regard to the respective proportions of all the ingredients which enter into the composition of ink.

Some of them prescribe fix parts of galls to one of sulphate of iron; others recommend three parts of sulphate of iron to one of galls.

Thus, according to fome, the quantity of galls ought very much to exceed the quantity of fulphate of iron; whereas, on the contrary, according to others, the quantity of fulphate of iron ought to exceed that of galls.

These differences are very considerable, and prove that no chemist, before Lewis, had seriously, and in a scientistic manner, enquired into the composition of this useful liquor.

It is far from being true, that the respective proportions of these ingredients is a matter of indifference, either with respect to the beauty of the ink, or the durability of the writing made with it. It is to a neglect of scientissic principles, that the public are indebted for such a variety of inks of all kinds; of which fome are very black, while others are very pale; and fome preferve their blackness a considerable time, while others grow pale, rusty, or yellow, more or less quickly.

We have shewn, that the blackness of ink is principally owing to the oxide disengaged from the sulphate of iron by the earth of the gallic salt, and dyed by the colouring matter with which it is surnished by the extractive part of the galls: whence it follows, that if these two ingredients are not employed in just proportions, the ink cannot be perfect.

If there is an excess of sulphate of iron, its oxide will not be sufficiently charged with colouring matter: nor will it be so covered as to be defended from the action of the air, consequently the ink will soon grow rusty and yellow.

If there is an excess of galls, writing made with it will be more durable; but it will not be of a good black colour, and will have a tendency to change to a yellowish brown.

If the respective proportions of these ingredients are in a mean between these two extremes, the colour of the writing, and the changes it will undergo, will be governed by the properties of the prevailing ingredient, and will be in proportion to its excess.

This theory agrees with the experiments of Lewis; by which we are shewn,

I. That

- 1. That equal parts of galls and fulphate of iron produced an ink which had a good black colour; but that writing made with it, and kept covered up for some weeks, became of a yellowish brown; which change took place in a few days, when the writing was exposed to the fun and the air.
 - 2. That when the quantity of fulphate of iron exceeded that of the galls, the change in the colour of the ink was more quick, and more firong, in proportion as the excess of the fulphate of iron was more confiderable.
 - 3. That when the quantity of galls exceeded that of the fulphate of iron, the colour of the ink was more lasting.

For instance, a mixture of two parts of galls with one of sulphate of iron, produced an ink which kept its colour better than one made with equal parts of each.

Whereas, by putting four, five, or fix parts of galls, the colour of the ink was more lafting than that of the preceding; but it was not to black.

Lewis fupposes, that the change which takes place in the colour of the ink is owing to the want of a sufficient quantity of galls; that, to render the colour of ink lasting, the quantity of galls ought not to be less than three times that of the sulphate of iron; and that it cannot much exceed

this proportion, without prejudice to the Blackness of the ink.

Upon this head I shall observe, first, that it appears, from what I have stated, that the change which takes place in the colour of ink, does not, as Lewis supposes, always arise from a defect in the quantity of galls, but may equally arise from an excess of that ingredient. It is indeed very true, that ink which has too fmall a proportion of galls, either grows rufty and yellow, or is of a yellowish-brown colour; but it is not less true, that ink which has too great a proportion of galls never has a good colour, and that the writing made with it is of a brown or pale colour, according to the proportion of galls: and this paleness increases, in such a way, that after a certain time the writing becomes fcarcely legible; and, although this change of colour may take place more flowly than that of the other, it is more complete and more prejudicial; that of the first being of fuch a nature, that the writing may be read a long time after the characters traced by the other are hardly to be diftinguished. An excess of galls, therefore, may produce a decay in the colour of the ink of a worfe kind than that which is produced by the want of them.

Secondly, equal parts of galls and of fulphate of iron, produce an ink of a good black colour, but which, when exposed to the air, acquires a 'yellowish

yellowish-brown, and not that yellow rusty colour which is acquired by those in which the sulphate of iron predominates; this proves, that the above-mentioned proportions come near to those which are required to produce a good and lasting ink.

Thirdly, my experiments have shewn me, that two parts of galls to one of fulphate of iron, are fufficient to produce an ink capable of fulfilling, in a proper manner, those purposes to which that fluid is applied; and that three parts of galls (which Lewis confiders as the fmallest proportion that should be used) is too much, because there then remains in the ink too great a quantity of gallic falt not decomposed; this is afterwards decomposed by the water, and its earth, in precipitating, carries with it a part of the colouring matter, and of the black oxide of iron: perhaps also the colouring matter of the superabundant quantity of galls, injures the black colour of the ferruginous precipitate, giving it a brown caft.

From all these observations, I think I have a right to conclude, that the respective proportions of the galls and the sulphate of iron should be such, that the latter should be entirely decomposed, and that there should rather be too great than too small a quantity of the former; but this excess should only be as much as is sufficient to

faturate

faturate the oxide of iron with colouring matter. It is, no doubt, with this view, that Lewis recommends three parts of galls to be used; but it is better to leave out one of those parts, and to put, instead thereof, a sufficient quantity of logwood, which would furnish to the ferruginous precipitate a great quantity of colouring matter, and does not contain any salt with an earthy basis, capable of rendering the ink liable to be afterwards decomposed, since it increases the blackness of the precipitate, without adding to its weight.

On the Proportions of Sulphate of Copper.

The effect of fulphate of copper being to render the colour brown, and to fix it, the quantity of it should be properly limited: it appeared to me, that the best proportion was an eighth part, by weight, of the galls. A larger quantity renders the colour too brown, and a smaller one is not sufficient to fix it.

On the Proportions of Gum and Sugar.

The proportions of gum and fugar should be regulated, not according to the quantity of galls, but according to that of the liquid.

Vol. IX. Dod My

My observations respecting the first of these subjects agree with those of Lewis. I found that the best proportion was, one ounce of gum to a quart of ink.

With respect to sugar, I found that two drachms and forty-eight grains was the best proportion for the same quantity.

On the Proportions of Liquid.

The proportions of liquid, relatively to the quantity of galls, vary very much in different formulæ. I have met with fome which prescribe four parts of water to one of galls; other formulæ, and their number is still greater, require fix parts. Lewis directs from eleven to fixteen parts of water.

I found that twelve parts of water to one of galls formed a very good ink.

Corollary.

By attending to what I have hitherto faid, it will be feen, that galls and fulphate of iron form the bases of ink.

That logwood is a very useful ingredient, because its colouring part concurs with that of the galls to give a black colour to the oxide of iron; and because it gives to the ink a more beautiful and perfect black colour, and to the writing, made with such ink, a greater body or confistence.

That the fulphate of copper is useful for deepening the colour of the ink, and rendering it more permanent.

That the use of gum is indispensable, to hinder the ink from spreading on the paper, and sinking into it; also to give to the ink a greater body of colour.

That fugar is necessary, to restore to the ink a part of that sluidity which gum, by itself, tends to take from it.

That the perfection of this liquor depends upon the respective proportions of the ingredients, either amongst themselves, or with the liquid made use of.

That water is the most proper liquid for the composition of ink.

Lastly, that the effect of galls may be affished by the use of logwood; but that this latter, notwithstanding its advantages, cannot supply the place of galls, as they form the essential basis of ink. On the Manner of operating upon the Ingredients, in order to make them into Ink.

Authors are divided in their opinion, whether it is best merely to infuse the galls in cold water, or to macerate them in warm water, or to boil them, more or less.

Some macerate all the ingredients together; others macerate or boil the galls first, and then add the other ingredients, either before the liquor is strained, or afterwards.

On this head I shall observe, first, that the object is not merely to extract the colouring matter of the galls, which might certainly be very easily done by means of cold water; but it is very doubtful whether we could, without the help of boiling, obtain a complete dissolution of the gallic earthy salt, which, however, is very necessary to the decomposition of the sulphate of iron. Besides, it is a known sact, that inks made with cold, or even with warm water, are pale when used, and do not become black till several days after; nor have they ever so sine a colour as those inks which have been prepared by being well boiled.

But, although it is necessary that the galls should be boiled, and also the logwood; that necessity certainly certainly does not extend to the falts and other ingredients: to boil them is rather an inconvenience, it being, without doubt, much better to throw them into the decoction of the galls and logwood, after having strained it.

Best Proportion of the Ingredients for the Composition of Ink.

Eight ounces of Aleppo galls, and four ounces of logwood, are to be boiled in twelve pounds of water, for the space of an hour, or until half the quantity is confumed.

The liquor is then to be firained through a piece of linen, or through a hair-fieve, into a proper veffel, and, if the quantity is found to be as above directed, namely, fix pounds, there may be added to it,

Four ounces of fulphate of iron, Three ounces of gum-arabic,

One ounce of fulphate of copper,

One ounce of fugarcandy,

The liquor is to be shaken, from time to time, to facilitate the solution of the salts, and more particularly that of the gum. When it is certain that all these are completely dissolved, the whole may be left to stand quietly for twenty-four hours; after which, the ink may be decanted

from the gross sediment which is deposited at the bottom of the vessel, and may be kept in glass or stone bottles, well stopped.

Observations.

This ink has a black colour, a little inclining to purple, in the bottles; but the writing made with it is of a beautiful black, and it preserves its blackness, without alteration, for a great length of time.

Each quart of this ink contains,

				2000年1000年
		oz.	drs.	grs.
Of galls,	14	2	5	20
Of fulphate of iron,	-	. 1	2	40
Of logwood,	4	1	2	40
Of gum,		1	0	0
Of fulphate of copper,		0	2	40
Of fugarcandy, -		0	2	40
Lewis uses, in each quart,				
Of galls,	7	3	0	0
Of fulphate of iron,	- 1	1	0	0
Of logwood,		0	5	24
Of gum,		1	0	0

He uses neither sulphate of copper nor sugar.

On the Preservation of Ink.

I have observed, that many persons recommend putting iron, others recommend putting galls, at the bottom of the bottles in which ink is kept. I never put any thing in mine; and yet I never observed that it suffered any change in its colour, or any other injury, even after it had been kept a considerable length of time.

Those who recommend galls for the abovementioned purpose, undoubtedly suppose, with Lewis, that the decay of ink is occasioned by the want of a fufficient quantity of that fubstance. But, befides what I have already faid on this head, I must observe, that I cannot comprehend in what manner fuch persons suppose the defect in queftion would be remedied by this addition. The colouring part of the galls is precipitated only by the oxide of iron; and the additional quantity of galls cannot hinder the precipitation of the black oxide: this precipitation is the cause of the alteration in the colour of the ink; which alteration, in this inftance, takes place, not from any want of blackness in the precipitate, but because it is diminished in quantity; the addition of galls is therefore quite useless.

Putting iron at the bottom of the bottles may, at first, appear more advantageous; but some observations

observations upon that expedient, will shew that it is also an useless one.

The end proposed in this case is, to replace, by fresh iron, that which it was supposed the fulphate of iron would, in a certain time, let fall in the form of oxide; to the loss of which the alteration in the colour of the ink was attributed. But I must observe, first, that when this falt is used in a proper proportion, it is almost entirely decomposed by the gallic falt, at the very instant of its mixture with the galls. Secondly, that the fulphuric acid, when converted into felenite, is incapable of again diffolving iron. Thirdly, that the fediment of ink which has been long kept, is not an oxide of iron in the state of ochre, but a black precipitate, fimilar, in all respects, to that which remains suspended in the ink, and causes its blackness. Fourthly, that this precipitate would not be replaced by fresh iron; because the iron would not find in the ink that matter which is necessary to give it colour, even suppofing that it found therein a free acid, capable of diffolving it, and afterwards a substance fit to produce the decomposition of the new falt which it had formed. In fhort, experience has convinced me, that ink may be preferved feveral years, in a state of perfection, without putting either galls or iron at the bottom of the veffels in which it is kept.

On the State of the Acids in Ink, and of the Attempts which have been made to faturate the Sulphuric Acid.

Lewis, suspecting that the loose sulphuric acid in ink was one of the principal causes to which its change of colour was owing, endeavoured to separate that acid by the addition of lime; but the ink was by no means mended thereby. A small quantity of lime did not much alter the colour, and a large quantity thereof turned it of a reddish-brown. Writings having been made with these mixtures, and exposed, for the space of two months, to the sun and the air, it was found that those which were made with the mixture which had the greatest proportion of lime were illegible, and the others had lost their colour more than if they had been made with common ink.

As the fulphuric acid is combined with the earth, in the form of felenite, there can be no loofe acid in the ink but the gallic acid, the weakness of which is such as to leave no room to suppose that it can act upon the black ferruginous precipitate; there is consequently no reason why the saturation of the acids should be attempted.

Vol. IX. Ee On

On the Trials which have been made of various Ingredients, as Substitutes for Galls.

It has been attempted to supply the place of galls by different vegetable substances, most of them taken from the class of aftringents: various solutions of iron have also been tried, as substitutes for the sulphate of iron; but experience has shewn, that these two substances are absolutely necessary in the composition of good ink.

The bark of the black-thorn or floe-tree, the roots of tormentil, and of biftort, the flowers of the pomegranate-tree, and the rind of its fruit, have all been tried, but were found to give to the ink made with them more or less of a greenish hue; none of these ingredients were capable of furnishing that black colour which is obtained from galls.

Sumach, which in the black dye may be used instead of galls, gives to ink a greenish cast, which renders it an improper ingredient in its composition.

Oak-bark appears to give the fame kind of black as galls; nevertheless, when it was used alone, it produced a bad kind of ink; and, even when the proportion of it was eight or ten times as great as the usual proportion of galls, it was

very far from producing an equal effect. Sawdust from oak-wood gives ink a very strong tinge of blue; which tinge it always retains, whatever proportion of oak saw-dust is used.

Various other astringents were tried, in conjunction with galls, and with logwood; they did not take from the colour of the ink, nor did they

appear to add any thing to it.

Lewis tried the juice of privet-berries, of mulberries, and of black cherries: all these produced inks which appeared more full of colour than if made with water alone, but they were less black, and become dull and rusty after being kept some time.

On the Trials made with various Solutions of Iron, as Subflitutes for Sulphate of Iron.

Solutions of iron in nitric and muriatic acid, produced inks which were too corrofive, and the colour of which was not fufficiently black; that made with muriatic acid inclining to blue, and that made with nitric acid being of a brownish-green.

A folution of iron in acetous acid, produced a very indifferent ink.

A foliation of iron in acid of tartar, gave to the decoction of galls a reddish-brown colour.

E e 2 A fo-

A folution of iron in lemon-juice, has a better effect than that made with vinegar, but is still inferior to the sulphate of iron.

Conclusion.

The refult of what has been faid is, that ink is a compound liquor, which owes its blackness to the oxide of the sulphate of iron; which is disengaged from its solvent by the earth of the gallic salt, and coloured by the extractive matter of the galls: it remains in the liquid in a state of suspension, not of solution.

2. That hitherto no ingredient has been discovered, that can be properly substituted for galls, in the composition of ink.

3. That logwood affifts the colouring action of the galls: that is, it renders the precipitate more black, without encreasing the quantity of it.

4. That fulphate of copper is advantageous, as it tends to fix the black colour of ink, without diffurbing its composition.

5. That gum is useful in preventing ink from fpreading on the paper, and finking into it. By preventing its spreading, the characters traced with it are charged with a greater quantity of colouring matter. Gum also terves as a kind of varnish, to defend the ink from the action of the air;

and

and contributes, in conjunction with the colouring matter of the galls, and that of the logwood, to prevent its decay.

- 6. That fugar has the effect of restoring to the ink a part of that sluidity of which the gum deprives it.
- 7. That fulphate of iron cannot have its place fupplied by any other ferruginous falt.

From these observations it follows, that all these ingredients are necessary in the composition of ink; that their place cannot be supplied by other substances; and, that the perfection of ink depends on their being combined in just proportions.

And, although all the ingredients which enter the composition of ink also enter that of the black dye, it is by no means true that all those which enter the latter composition are proper for making ink. Besides, the proportions of them, either with respect to each other, or with respect to the liquid made use of, are not the same.

Yet, notwithstanding the difference between these two compositions, the chief of the foregoing experiments and observations on galls, and those on sulphate of iron, may be equally applied o both of them. Appendix, containing some Experiments relating to the Subject of the foregoing Differtation.

Three ounces of fumach, and two ounces of fulphate of iron, produced (by treating the fumach in the fame manner as the galls) an ounce and a quarter of precipitate. Two ounces of galls would have produced two ounces and a quarter of precipitate.

Four ounces of a folution of iron in vinegar, produced (by means of fixed alkali) two ounces and a quarter of precipitate.

Four ounces of a folution of iron in acid of tartar, produced (by means of fixed alkali) an ounce and a quarter of precipitate. Four ounces of fulphate of iron would have produced an ounce and a half of precipitate.

XXVII. Lift of Patents for Inventions, &c.

(Continued from Page 144.)

George Blundell, of the parish of St. Matthew, Bethnal Green, in the county of Middlesex, Manufacturer; for a machine for the purpose of saving suel, and preventing dirt or dust from sires, which he calls the *Economical-Re*ceiver. Dated May 3, 1798.

WILLIAM JONES, of the city of Bristol, Mill-wright; for a machine for the purpose of more readily mixing malt, or other substances, with sluids; whereby the effence or spirit of the malt, or other substances intended to be acted on by water, or other sluids, will be more perfectly and expeditiously extracted than by any other method hitherto invented. Dated May 8, 1798.

ROBERT FRITH, of Salford, in the county of Lancaster, Dyer; for a chemical method of dying different permanent colours upon cotton, linen, woollen, and filk. Dated May 25, 1798.

WILLIAM

WILLIAM SANKTER, of Horseheath, in the county of Cambridge, Farmer; for a plough for the paring of land, which he conceives will be of great public utility, and peculiarly calculated for the saving of manual labour. Dated May 25, 1798.

John Champion, of the city of Bristol, Manufacturer of Brass, Copper, and Iron Ware; for a method of making wire from rolled and slit iron, either foreign or English, put in operation by various powers. Dated June 2, 1798.

GEORGE POMEROY, late of Boston, in North America, but now of London, Merchant; for an apparatus and machinery for the manufacturing of tobacco and fnuff, and for other purposes. Dated June 5, 1798.

JOHN PALMER, of Maxtock, in the county of Warwick, Yeoman; for a new invention in the construction of apparatuses used for clearing grain from the straw, and for pulverizing the same. Dated June 5, 1798.

JONATHAN HORNBLOWER, of the borough of Penryn, in the county of Cornwall, Engineer; for a machine or engine for raifing water, and for various other useful purposes in arts and manufactures, by means of steam and otherwise. Dated June 8, 1798.

Printed by JOHN NICHOLS, Red Lion Paffage, Fleet-Street, London.

ARTS AND MANUFACTURES.

NUMBER LIL

XXVIII. Specification of the Patent granted to Mr. DAVID FREARSON, of Liverpool, in the County of Lancaster, Merchant; for Machinery and Operations for the Purpose of saving Fuel, in the Process of evaporating Water from Solutions of Salts, the waste or cast-off Leys of Soap-makers, and which may be applicable on other Occasions, where Evaporation, or a Separation of Water, forming either wholly or in Part a desolving Fluid, from the Substance or Substances held in Solution, is required.

Dated May 21, 1792.

To all to whom these presents shall come, &c.

Now know ye, that the principles on which the
patentee rests his pretensions to his Majesty's letters of licence, for an exclusive right to the practice and emoluments of his invention, are, geneVol. IX.

Fig. rally

rally speaking, these. As oily, soapy, gelatinous, or mucilaginous matter, when intermixed with aqueous folutions, and gathering upon their furface, would materially obstruct the progress of evaporation, when promoted by the principles to be proceeded on, all fuch are to be removed, as much as is possible and convenient, by filtration, and, at proper periods during the process, to be skimmed off. After having, when requifite, undergone fuch filtration, for the forementioned purpole, or for removing other impurities which it may be defirable to feparate, the folutions of falts, the waste or cast-off leys of soapmakers, or other mixed folutions, (from which water, forming either wholly or in part a diffolving fluid, is required to be evaporated or feparated from the substance or substances held in folution, and with which a part of the fubstances intended to be left behind may occafionally fly off,) are to be exposed to the atmosphere, in shallow ponds or refervoirs, which are to have various machinery affixed to them; by means of which, a part of the folutions may be fucceffively taken up, and spread over the furfaces of the machinery appropriated to that purpose, and thus have an increase, division, or extension of their furfaces farther exposed to the atmosphere, to be acted on by the fun and air, and are to be protected, by fuch machinery, from rain or dew falling

falling into, or incorporating with them. The operations and machinery he judges most proper to effect this purpose are as follows; and, though machinery of other forms and other materials than those he points out, may undoubtedly be constructed and contrived for the same use, yet, as they must affuredly be some way or other imitations of these, and operate upon the same general principles, he trusts and hopes that his study and expence to accomplish this business will not be suffered to be lost to him, by attempts to evade his patent on such grounds.

I. The Receiving Reservoirs, for Solutions required to be kept or filtered. The foap-makers waste levs. or any other folutions of fuch description, will require refervoirs for their reception, of dimenfions proportioned to the quantity whence the water is required to be evaporated, and which, with the fucceeding refervoirs, may be fufficient to contain a confiderable portion during the winter, or any long continuance of wet unfavourable weather. These dimensions will necessarily be regulated by circumstances, such as, the extent of the refervoirs and machinery to which they are attached, the quantity likely to be received in winter, and during weather not favourable to the progress of evaporation, &c. They may be constructed of various forms and materials, but must be so tight as not to admit the solutions, in any F f 2 material

material quantity, to penetrate or exude through them. If they are formed in the ground with clay and bricks, or clay, bricks, and cement, the best form will be cylindrical; the base of the cylinder will be parallel with the horizon. These I will call, to distinguish them from the others, The Receiving Reservoirs.

H. Filtration, and the Filtering Refervoirs. When any folutions require filtration, to take from them any obstructions to evaporation, or earthly impurities, there must be another reservoir constructed, fimilar to the former, and adjoining thereto, over which must be placed large square-edged bags or filters, fastened to cords at their edges; the bottoms of which, when fuspended and containing the fluid, may incline towards a spherical or conoidical form, of a moderate depth. These square-edged filtering bags, formed of canvas, hair or other cloth, or ftuff fit for the purpofe, (into which the folutions must be pumped, or fome other way run in,) must be secured, by noofes at the angles, to upright staffs or pegs placed at the end of rods, running square with each other in an horizontal direction; from which, to the rods, the noofes may be at any time flipped, fo that the two opposite points of each parallel fide of the fquare (or it may be oblong) horizontal line of direction of the noofes upon the rods, may be brought or drawn to approach each other

other, and the residuum in the filters pressed. In addition to the above mode of filtration, he proposes (when the folutions are so impure as to require it) to divide these filtering reservoirs into two parts, by a partition; to put coarfe fand at the bottom of each division, so as to occupy a fpace of fome inches, left for the purpose, between the bottom of the dividing partition and the bottom of the refervoirs, and to come up a little above the bottom of the partition. The bottom of the division, over which the filtering staffs are suspended, must decline a little towards the bottom of the other; and, upon the fand in the former, is to be placed coarse hair-cloth, canvas, or other stuff, fixed to poles, by noofes, with cords, fo as to be drawn up at pleafure, and the refiduum found upon it, after the folutions have paffed into the other divisions, taken away. These filtering, as well as the receiving refervoirs, should have flight sheds or roofs, to keep out the rain. The foap-makers wafte leys will particularly require as perfect a filtration as can conveniently be had; as the foapy and gelatinous matter they commonly contain, if not separated, will gather upon the furface of the folutions, and in a great measure retard the progress of the evaporation of the water. Other folutions, to which the principles of this patent are applicable, may also require an attentive filtration, as well as thefe.

III. The Evaporating Reservoirs. Either the folution which have passed filtration, or those . which do not require to be filtered, are to be run or pumped into shallow pits or refervoirs. evaporating refervoirs are to range and be placed so as to extend from east to west, or nearly in that direction, in the longer or oblong fide of their square, and from north to south in their fhorter fide or breadth; they may be from about nine to about fourteen inches deep, and are to be fo constructed as to retain the folutions, and of fuch materials as may be had on the cheapest terms, and be effectual for the end in view, (as well as the other refervoirs before mentioned,) which will of course vary in different situations, circumstances, and places, respecting which, I shall endeavour to give some instructions, or at least hints, in my remarks on the materials.

IV. The Materials of which to conftruct the Refervoirs in general. There being a great variety of materials of which all the afore-mentioned refervoirs may be conftructed, I shall endeavous to point out those which may be generally the cheapest and most fit. If good clay is to be had in the ground, or near it, so as to be had at a low price, I would use it, well tempered, and close rammed down, as a retainer for the sides and bottoms of all such of them as are placed or sunk in the ground. The receiving and siltering refervoirs

fervoirs may be formed of bricks, fet in fuch clay, at about fix inches thick from them, or, as before intimated, these may be formed wholly of wood, in the way the workmen of the city of London conftruct what they call backs, but will be expensive. The bottoms and sides of the evaporating refervoirs may be covered with boards, and fecured at the ends and middle upon frames or joifts, stretching the length of the reservoirs; or with fquare-edged bricks on flat or fquare tiles; or with bricks or tiles covered with, or fet in, tarras, or any fuch like good cement or mortar. In the fituation where it is first designed to apply his machinery and operations, near the city of London, to the evaporation of water from the foap-makers waste or cast-off leys, there not being proper clay in the ground, or near at hand, and the ground lying rather low and disposed to be damp, it is intended to form the evaporating refervoirs wholly of wooden boards, close jointed, fo as to retain the folutions; to rest them upon logs of wood, or other pillars, being supported from pillar to pillar, by fufficient bearers, at about a foot from the ground; and to excavate and take away a part of the earth underneath them, fo as to leave room for a person to pass occasionally through, and examine whether they be fo tight as not to admit of the folutions to exude through the joifts, or any accidental opening or crevice.

It is impossible to ascertain minutely now, by directions and description, the greater eligibility of one material rather than another, of which to construct these reservoirs, the choice depending so much on fituation, the value of the folutions and other circumstances observed on. The fituation must be viewed, and proper estimates made of various articles, by which the judgement may be guided. It may however be remarked, that refervoirs constructed of wood, if not objectionable, as to coft, will be better for retaining alkaline folutions than those made of most other cheap materials; for alkaline compounds, in which there is an excess of alkaline falt, will take up into folution (and fo may be faid to corrode) filiceous and argillaceous earths, of which common clay is almost wholly composed, and also the filiceous or fandy part of the cements called mortars or tarras, in proportion to the excess of alkali, whether vegetable or mineral. Weak or mild alkaline folutions will be long in corroding, or taking into folution, clay, or the filiceous part of well prepared cements or mortars; but he would caution those who may follow him, or may use his invention, that an exudation or loss of the folution may take place, when they are not aware; for the idea that the water may alone exude, and the contained falts remain, is a mistaken one. Salts will pass, with their water of folution, even through glazed

ations

glazed earthen-ware, as he has often experienced; like remarks may be made respecting some acid folutions. Reservoirs constructed with bricks and common mortar, and well covered, or of wood covered, either wholly or only at the joints, with pitch, may be very proper and cheap, in some cases, so retaining such solutions as will not decompose or corrode the pitch. And it may be observed, that black, being the colouring material most heated by the direction of the rays from the sun, (as appears by its absorption of them, and from experience,) may be applied, in some instances, to the evaporating reservoirs and machinery; so that, by increasing the heat, the evaporation may be helped. I come now to,

V. The Evaporating Machinery, to promote Evaporation, and protest the Solutions from Rain or
Dews falling into or incorporating with them. And
first, the wheel machinery, resembling the fly of
a smoak-jack, but placed vertically, and its covers. The use and dimensions of this, as well as
of every other contrivance intended to effect the
purpose, must necessarily be regulated by situation, and the quantity designed to be exposed to
evaporation. Suppose the evaporating reservoirs
to be from about two to three hundred feet in
length, extending from east to west, and about
sisteen feet in breadth, from north to south, which
may be the most proper dimensions, in many situ-

Vol. IX. Gg

ations where the principles of the patent are adopted; then, over these reservoirs are to be placed roofs or frames, formed of thin boards or framed canvas, (or any other coarse cloth or stuff sit for the purpose,) from which the rain ray run off, as from an umbrella, and not penetrate through, and mix with the solutions. These are to be affixed, by strong hinges, to poses or pieces of wood, extending from east to west, like the ridging of the roof of a house; and are to be supported by other posts, poles, or pieces of wood, placed perpendicular to the horizon: I will call them,

VI. The moveable Roofs. If the evaporating refervoirs are about fifteen feet broad, and the wheels or flies (which will hereafter be described) are about twelve feet diameter, these moveable roofs may be each about fifteen feet long; and, at the ends of the frames (or the pieces of wood to which the boards of the frames, or the framepieces formed of canvas or coarfe cloth, or the like, are fecured,) are to be fixed poles or fraffs, by staples or hinges, so as to lift up the roofs to a few degrees above the horizontal level of the folutions below, and there fupport them; or to let them down, that they may form a covering to protect the folutions from rain or dew; for which they must be sufficient, and must be made tight, or be covered, at the joints where

the hinges are, fo as not to admit the rain to fall through at the ridges: below these moveable roofs or coverings, must be fixed,

VII. Wheels or Flies, with their axles refting towards the north and fouth, in proper bushes or fupporters, rifing from, and fastened to, the sides of the evaporating refervoirs. The diameter of the wheels will of course extend towards east and west; and, to the extremities of the parts compofing the flies or wheels, are to be fixed thin boards, extending perpendicularly from the line of their circumference, towards north and fouth. To these must be affixed other pieces, both at the ends and going lineally with the circumference of the wheel, fo as to form a kind of shovel, to take up and disperse the solutions. These fly-wheels are to be fo constructed as to be fet in motion by the wind, when blowing with a needful degree of ftrength, and in certain directions; and are to be fo hung upon their fupporters, that the shovels, as they move, may dip into the folutions, take up, and difperfe them over the furfaces of the wheels, and the furfaces projecting from them, that they may be exposed to the effects of the fun and air, and the aqueous parts carried off in vapours, or evaporated. The fupporters, in which are placed the buthes on which the axles of the wheels are to rest and move, must have at the top, frames or pieces of wood, extending from them at right angles, into each of which are to be inferted three or four bushes, that the axles of the wheels may be occafionally moved and shifted into them, so that the lines of their diameters (the wheels) may be placed from towards east and west, to towards north and fouth, or fouth and nor h; that they may be properly exposed to the direction of the wind, by which they may be kept in motion, and revolving upon the axles: the axles are to be fastened into the bushes by proper hasps. When the wind does not blow with fufficient force, or in a proper direction to give motion to the wheels; when loaded with the folutions adhering to them, and to the projecting materials defigned to make an increase of the surfaces of fuch folutions, they must be moved by some other power. These fly-wheels must have various substances fixed to them, such as reeds, or branching twigs of trees, projecting from their furfaces; but they must not be so numerous, or fo heavy, when loaded with the folutions taken up and dispersed, as materially to affect their being kept in motion by the wind; nor must they be obscured, but fufficiently and fully exposed to the effects of the fun and air.

VIII. Instead of, or in addition to, the abovementioned fly-wheels, (designed to be operated upon and set in motion by the wind,) wheels may be placed in like manner, made of thin boards, framed

framed cloth, &c. (of the full area and circumference of a circle,) the diameters of which must necessarily depend on circumstances, (before alluded to;) and these may be covered on both ades, especially towards the fouth, with various fublances projecting out, and fixed to them, for the purpose of dividing and increasing the furfaces of the fluid; and must have shovels fixed to them, in the fame manner as the fly-wheels. These wheels, as well as the former, must have, at the north end of each of the axles, a projection of a few inches; into which, cross staffs must be fixed, at right angles, that they may be turned round in fuccession, and the folutions taken up, and dispersed over the surfaces, to keep them wet and dripping; which must also be done to the fly-wheels, when they are not kept in motion by the wind. Various other mechanical powers may also be applied for this purpose, and fo as to keep the wheels in continual motion.

IX. The Evaporating Machinery, resembling a Drawbridge, or the Frame-Machinery. This class of machinery may succeed the others, or not; situations and circumstances can alone determine. They may be constructed cheaper than those before described, of proportionable size; may be worked where the fly-wheels cannot, for want of a sufficient current of air, unless motion be given to them by some other power, and will, for many reasons.

reasons, be generally preferable to the plain wheels, and to both, in respect that the folutions may be more eafily covered and uncovered by them, as the moveable roofs will require more ffrength and labour to raife and let them fall, and of course more time, or more hands; hence it may be, in many instances, best to work with these alone. Whether they do or do not succeed the operation of the former upon the contents of the evaporating refervoirs, they are to be confiructed thus. On the north fide of the evaporating refervoirs, pillars are to be fet up, and fixed in the ground, of fuch heights and fcantling as may be conformable to the breadth of the refervoirs, the extent of furface wanted, and the extent of the frames when loaded with the folutions. Suppose these refervoirs to be from about two to about three hundred feet long, and about fifteen feet wide, as has been supposed before to be generally most convenient; then he would have the pillars put down at about twelve or fifteen feet diffance from the centre of the perpendicular direction of each other, to be about feventeen or eighteen feet high, about nine inches broad, and of firength proportioned to the weight they are to support; they must be funk in the ground, to such a sufficient depth that they may fland firm, and have ftays, on the north fide, at the bottom. Thefe pillars being placed at about fix inches diftance from

from the evaporating refervoirs, in the space between them must be put down other pillars, of the breadth of the pillars, and fo thick as exactly to fill up the space, which are to be funk into the ground about fix or nine inches deeper than the pillars. On the tops of each of these, on a revel with the north edge or brim of the refervoirs, (which must be a little lower than the fouth edge, that the folutions, when the frames are dipped, may not be thrown over the latter,) are to be affixed, with bushes and forelocked bolts, to iron eyes or loop-holes projecting by strong iron straps from the fouth side of the pillars, two posts or supporters to the frames, which I will call the frame-supporters; of such length that they may exactly meet and fall into the opposite side of the refervoirs, and so, resting in part on those logs, which I call frame-logs, and partly on the bolt like the pin of a hinge paffing through them, they may be raifed towards a perpendicular height, or let fall at pleafure. To other frame-logs, or to other pillars to the right hand and left or east and west of these are to be affixed like frame-supporters, and in the same manner. Thus, three pillars will comprize in their extent two fets of this part of the machinery; to the lower edge of two of these frame-supporters are to be fastened, from pillar to pillar, thin boards of wood, or frames of well-stretched canvas, or other cloth or stuff. If boards

boards be used, they must lap, or be fixed at the edges, one over another; fo that, when the frames, which I will call evaporating-frames, are fuspended at an angle, suppose thirty degrees, they may form a roof or cover, from which the rain, as it descends, may run off, and also the folutions, as they are taken up upon them. On the fouth or lower fide, the boards may be strengthened, and fecured to each other, by battens running across them. On the tops of the pillars are to be fixed, by flout hinges, with the pins of the hinges on the north fide of the pillars, and ftraps going round the tops of the pillars, two bars or pieces of wood, fo as to conftitute levers or balances; when thefe are suspended horizontally, a cord or chain must drop from their fouth ends vertically, and be fecured to the frame-fupporters. These bars or pieces of wood, which I will call evaporating-levers, must be made tapering; fo that, when they are suspended in an horizontal direction, the fouth end of the lever may be the fmaller and lighter, and the north end the larger and heavier. If the evaporating refervoirs be about fifteen feet wide, I would have the fouth end of the evaporating levers from about twelve to fifteen feet long, and the north end about feventeen to eighteen feet long; where they must be joined by other pieces of wood, of fuch weight that, with the aid of the strength of a man, they

may easily counterpoise the evaporating frames loaded with the solutions, and move them. The south sides of these evaporating frames are to have reeds, branching twigs of trees, or other light materials, fastened to them, but not to project so far as to prevent their dipping properly into the solutions: these will not produce an increase of surface by their number, but occasion a dripping after being immerged. When the solutions are very mach concentrated, they may be removed, or else they must be afterwards washed with weaker solutions, or a part of the machinery may be wholly without them, for solutions in that state.

The Operations with the Frame-Machinery. The evaporating refervoirs, and this part of the machinery, being thus prepared, the refervoirs must be nearly filled with the folutions from the receiving or filtering refervoirs, and the frames let down and dipped into them by the levers, fo that the extremity of the upper furface of the fouth end may be dipped or plunged from two to three inches; after which, the frames are to be raifed up, and the levers fixed, by means of a cord, or other fuch contrivance, to the pillars, fo as to support the frames standing towards a perpendicular direction, but inclining a few degrees to the fouth; both the north and the fouth fides of the frames, and the projecting furfaces from the Hh Vol. IX. latter,

latter, will thus be wetted, and exposed to the effects of the fun and air. At that which will be the lower end of the frames, when thus raifed, must be left an opening through its whole breadth; fo that, when the fluid is taken up upon the north fide, as it runs down, it may pass through this opening into the refervoirs; and, that this space may be made the most of, as to the effect of evaporation, there are to be reeds, branching twigs of trees, or other lings of that fort, fuspended from the bottom of the frame above; yet not in fuch number, or fo close to each other, as either to impede materially the passing of the fluid, or cause it to fly forward to the ground and be loft. When the wind blows with a great force, thefe reeds, &c. may be removed, that the folutions, as they are divided in paffing through them, may not be blown away. The doing of this depends entirely on their value, and the degree and force of the wind; during fair weather, people must thus proceed, plunging, wetting, and raifing these frames successively, till the evaporation be carried on to fuch a degree, that it is no longer prudent to attempt its continuance without the aid of fuel: when the folutions must be run off into refervoirs, to be put into iron pans, or run off directly into the pans, that the evaporation may be perfected in the usual way; and, if any falts have crystalized, and fallen to the

the bottom of the refervoirs, they must be taken away, and treated as is customary. As the evaporation will proceed quicker when the folutions are weak and contain much water, than when they are concentrated and contain but little, the evaporating refervoirs must be divided into compartments, (the number depending on the length of the refervoirs,) by boards running across them, to which the frame-machinery must be fo adapted, where they are put, that the edges of the frame-fupporters may pals the edges of these dividing boards, and dip, with the frames, into the contents of the refervoirs. The wheel or fly machinery must also be adapted properly to these compartments. The bottoms of each of the compartments into which the folutions are first put, must be nearly on a level with the surfaces of the adjoining ones, into which, when the boards are lifted up, the folutions concentrated to a certain degree may pass, and be treated in the like manner; then passed or run into a third, and fo on, just as circumstances, and their degree of strength, may point out. When rain or dew falls, the frames must be let down, so as to form roofs for the protection of the folutions, from which the water may run off; and the openings of the lower parts of the fufpended frames must then be covered up by light frames, as long as the evaporating frames are broad, which may Hh 2

be placed upon stays fixed to the frame-supporters, and enter, as into a groove, below the bottom of the principal frames, where they may be fecured, and fo receive and carry off the water. Or fome folutions of little value may be covered up, by letting fall a flap, either of thin boards or framed canvas, jointed by canvas, or any other proper material, to the edges of the frames above. On the fouth fide, painted or payed canvas, or other can cloth or proper stuff, must be raised an sastened to that edge of the frames extending from the fides of the refervoirs, to protect the folutions on that fide, when the frames form a roof to carry off the water. Before these frames for the openings are fixed, or the flaps let down, fome of the rain should be fuffered to pass over the surfaces of the frames, (which will refemble a roof,) through the openings into the refervoirs, to wash into them such part of the folutions as may be adhering, that they may not be carried on to the ground and be loft, especially if they be concentrated and valuable. In showery weather, when rain is often expected, it will be proper to work only with the fouth or lower fide of the frames, and omit to dip the upper, keeping on the moveable frame, or the flap down, but the former a little shoved up into the grooves, that the folutions may be more effectually preserved, particularly if they are ftrong

ftrong in falts. With the above general descriptions and directions, are included fuch operations as more particularly belong to valuable folutions. I shall now observe upon some particulars, which may more especially relate to the evaporation of water from the falt water of the fea. The fea water, being let into large open ponds or refervoirs, as is done at Lymington, in the fouth of England, and in France, that the earthly impurities may in fide to the bottom, and fuch part of the water be waporated in these open ponds, as the state of the weather and other circumstances may conveniently admit, must afterwards be passed into evaporating reservoirs, to which these principles, machinery, and operations, may be applied. The evaporating refervoirs for this purpose are to be constructed in much the fame way as those before described; but it is not requifite that fo much care and expence should be employed to make the first ranges of them tight, for retaining the folutions while they are yet weak and but little concentrated, because of the small value of sea water, compared with fuch folutions as the foap-makers waste leys, or others for which a considerable price is or may be paid. These first ranges of refervoirs and machinery, defigned for the reception of the fea water, which has (or has not) undergone a certain degree of concentration in the open

open ponds, may be formed of clay only, or any other cheap material, which will pretty well retain the fluid. But, in this case, they must either be of fuch fufficient depth, that the dipping of the evaporating frames, or moving of the wheels, may not cause the close rammed prepared clay or mud made use of to be mingled with the folutions, (fea water, or falt brine,) fo as to make them muddy, or else, after passing these, they must be run off into other large and deep reservoirs, that the earthy preticles may subfide, and the brine or folutions be cleared; and filtration, as has been before described, may fometimes be employed to advantage for this purpose. The fucceeding refervoirs, especially those in which the falt is defigned to be formed, (by the cryftalization which will take place on the evaporation of the water,) must be made with much the fame care as those described before, in IV, and the fluid paffed in the fame manner from one to another; as the concentration advances, constant attention must be paid to skim off the impurities which may arise upon the furface, as before directed. In fummer, and when the feafons permit, as much falt will of courfe be fuffered to form or crystalize, and be taken up (or, as is termed, drawn) as is possible. When falt is not formed or cryftalized, in the evaporating refervoirs, by the operation of the fun and air, the falt falt brine folutions are to be brought as near as prudence will admit to the point of faturation. and are then to be run off into refervoirs, where they may be kept, to be farther purified by the fubfiding or precipitation of the earthy impurities, and afterwards put into iron pans, (or directly run off into the pans,) to be boiled down to falt in the usual way; and the falt brine which may remain in the refervoirs, after falt has been formed and drawn, is to be treated in the same manner. But it may be observed, that if the boiling or evaporation of water from the falt. by the aid of fuel, be conducted flowly or moderately, the falt will crystalize in larger grains. and be more perfect for the preservation of animal fubstances than when they are fmall, and produced by quick boiling to promote evaporation.

Observations. Wooden boards, for the evaporating frames and moveable roofs, may be preferred to canvas or other cloth, for all those solutions which would tend to destroy the cloth, as all which contain an excess of alkaline salt certainly would. If canvas, or any fort of cloth, be used for such solutions, it ought to be well painted or payed, which would be expensive, and even that would secure it but imperfectly from their effects. This objection to framed cloth or canvas does not extend to the salt water of the sea;

for, as evaporating frames or protecting covers constructed with such materials would be much lighter than if of wooden boards, they may be more eligible, as they would require less power and strength to work and apply them. For evaporating water from the falt water of the fea, open cheap canvas, or fuch like cloth, or hair cloth, ftretched and fixed to wooden frames, made no heavier than is necessary, may be the best, both for the moveable roofs and exaporating frames; and the reeds, branching twigs, &c. may be attached to the wooden frames of the latter. These may very well be worked by fingle levers, fixed in the manner of the double ones, but to pillars standing to face the middle of each frame, at the distance of a few inches from the reservoirs; and the frames, in this case, are to be hinged upon the frame logs, in the way before described. but with eyes or loop holes projecting by iron straps from the frame logs themselves. These frames may also be hinged in many other ways. The evaporating frames, of whatever material they be made, may be taken up and let down by fingle levers, or by cords and pullies fixed to pofts, high fufpended rails, &c. but he apprehends not with fo much dispatch and steadiness as by the double levers described in IX, particularly if they be wholly of wood, and confequently heavy. In a valuable treatife upon falt, the late Doctor Brownrigg

Brownrigg has fuggefted fome principles and · modes for promoting evaporation from the falt water of the fea, or any falt brine, which have 'fome conformity with a part of the patentee's machinery and operations. He has therefore folicited for an exclusive right to the use of new and improved machinery and operations, though he cannot learn that the ideas of Doctor Brownrigg have ever been brought to use. He is informed, indeed, that fuch machinery and operations as the Doctor has pointed out, have been made trial of, for evaporating water from fea water, but without fuccess, as might be expected, when the expence is compared with the want of efficacy of his plan; and he takes notice of this, merely that no person may attempt the invasion of his patent, under pretext that it is only an improvement. He trufts and believes, that on the whole, his machinery and operations may be pronounced to be effentially new, (and he hopes ufeful,) at least in relation to their object; but he has his Majesty's letters of licence for new and improved machinery and operations, which he has endeavoured to describe and make discovery of, as trnly, fully, and openly, as he has had ability to do. In witness whereof, &c.

XXIX. Specification of the Patent granted to Mr. William Jones, of the City of Bristol, Millwright and Engineer; for a Machine for the Purpose of mixing more readily and intimately Malt, or other Substances, with Fluids; takereby the Esfence of the Malt, or other Substances intended to be acted on by Water, or other Fluids, will be more perfectly and expeditionsly extracted than by any other Method bitherto invented.

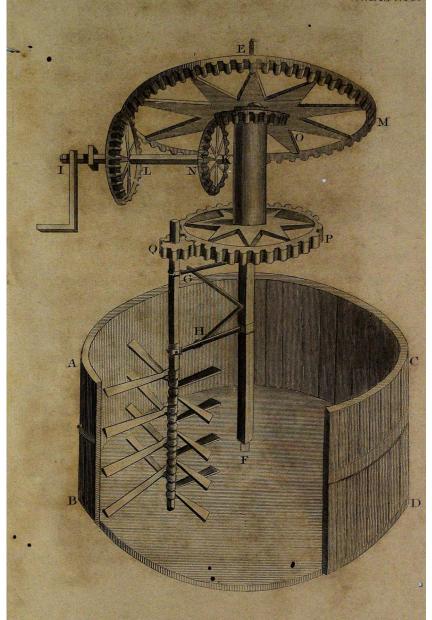

WITH A PLATE.

Dated May 8, 1798.

To all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said William Jones do hereby describe and ascertain the nature and principle of my invention, as follows; that is to say, my invention consists in such a construction of machinery, to be fixed to, in, or about any mixing or mashing vat or tub, as, on being put in motion, by the application of any power to be derived from water, wind, steam, animals, or otherwise, shall occasion the malt, meal, water, or other ingredients in the tub or vat, to mix in-

timately together, and so to change their relative fituations, as to cause the essence of the malt, meal, or other fubstances intended to be acted on by water, or other fluids, to be more perfectly and expeditiously extracted than by any other method hitherto invented; which machinery is delineated and described in the annexed figure; that is to fay, A B C D (Plate X.) represents a section of a tub or vat, in which the operation is to be performed; to, in, about, or over which, such framework is to be fixed, as shall be sufficient to support and fecure the feveral fpindles, wheels, and other machinery hereinafter described; that is to fay, E F, is an upright spindle, of iron, wood, or other materials, to which is ftrongly fecured a frame GH, and also the bevel wheel M; which fpindle rests and turns on a centre-focket, in the bottom of the vat or tub, at F, and in a collar at E. IK, is a horizontal fpindle, turning in collars fecured to the frame-work, on which are fixed the bevel-wheels L and N; on the rotation of which horizontal fpindle, the wheel L communicates motion to the wheel M, together with the upright spindle to which it is fixed; whilft the wheel N puts in motion the wheels O and P, which are fixed together upon a hollow box or spindle, which is fitted to, and turns upon, a round part of the upright spindle EF. At the fame time, the wheel P turns the wheel Q, which I 1, 2

is fixed on a spindle turning in a frame GH; and which last-mentioned spindle is continued down into the tub or vat, (into which the materials to be mashed are put,) having, at certain distances, vanes of iron, or other substances. fixed round it, at fuch angles with each other, and fuch inclination or dip, that when the lastmentioned fpindle revolves, the faid vanes or knives shall take in the whole, or nearly the whole, of the space within their sweep or extent. And, as the whole of the faid frame of vanes or knives is carried round the tub or vat, in the time in which a certain number of its own revolutions are accomplished, the whole of the materials to be mashed or mixed are in turn divided and blended together; and, by the inclination of the vanes or knives, are raifed from the bottom to the top, in one part of the tub or vat, whilst a contrary motion takes place, in another part of the tub or vat. In which kind of planetary motion in the faid machine, I hereby declare the excellence of my faid invention principally to confift, by whatever machinery it may be accomplished. In witness whereof, &c.

XXX. Specification of the Patent granted to Mr. ISAAC WHEILDON, of Coptball-court, Throgmorton-fireet, London, Packer, and Mr. John Bowler, of Bear-lane, near Blackfriar's-Bridge, in the County of Surrey, Machine-maker and Engineer; for their Method of making and working Presses, of all Kinds and Dimensions, and particularly Packing-Presses and Hot-presses; by which Goods are packed and pressed with much less Labour and Expence than by the common Presses now in Use, and considerably closer, and more even; and the various Sorts of Goods are, by this Invention, very much improved.

WITH A PLATE.

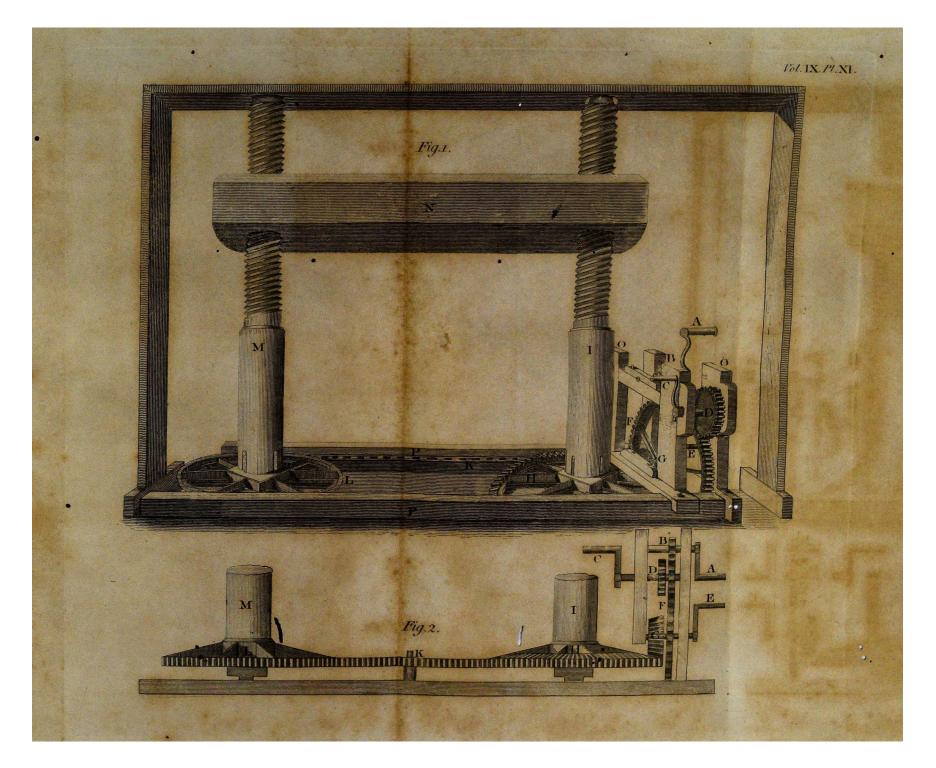

Dated April 26, 1796.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, we the said Isaac Wheildon and John Bowler do hereby declare, that our said invention, and the means of performing and putting the same in use, is described in manner sollowing; that is to say, the principle on which our invention is sounded, is the applying of chain, cog, or any other kind of wheel or wheels, of various

various forms and fizes, and placed in various fituations, (to be worked by a handle or handles,) which may be affixed or annexed to any kind of press or presses, for the purpose of power in presfure, which has the advantage of compressing any substance capable of pressure into less compass, with less labour, than the presses now in use. In pursuance of the said. letters patent to us granted, we do hereby afcertain and describe our faid invention, for which fuch letters patent to us were granted; premifing, and particularly meaning, that the fize, dimenfions, and powers of our faid presses, may be so varied and applied to the various purposes to which they are applicable, as to prevent the specifying any particular fort or fize. Their component parts may be made of wood, iron, brafs, or any other fubstance or fubstances. capable of being brought to the shape and uses hereafter described; and, in order that such defcription of our faid invention may be the more eafily explained and comprehended, we have drawn, in the margin of these presents, a press, according to our faid invention, which may be used for packing and pressing bale, or any fort of goods of great bulk, capable of preffure; and. by varying the dimensions of the component parts of the press here described, the invention may be applied, with equal advantage, to a press or presses of any other fize than that here described.

Fig. 1. (Plate XI.) represents a perspective view of a packing-prefs, according to our faid invention. A, is a handle, that by turning gives motion to the machinery, by its turning the pinion B. C, is another handle, for a quicker motion, which is annexed to the axis of the larger pinion D; and E is another handle, which is occasionally fixed to the axis of the spur-wheel F, to be worked by a man flanding in a hole beneath it; and, on the fame axis, is a pinion G, which acts in a tooth and cog wheel H, and which is fixed to the bottom of the forew I. K, is a chain, which is connected with the cogs of the wheel H, and to the cogs of the wheel L, which turns the other fcrew M, (which fcrews rest on pivots,) and which causes the nut N to come down exactly level upon the fubstance to be preffed or packed, with an aftonishing power of pressure; and, by turning the handle or handles the contrary way, it causes the nut N to rise to its proper station. OO, is a frame, with the multiplying wheels fixed therein, which is annexed to an end of the press; or it may be carried to its fide, if necessary; and it may be inclosed with a covering or case, to keep it from dirt or injury. PP, is a frame for a platform or case to be fitted to, or upon it, which covers the whole of the bottom machinery.

Fig. 2. reprefents a front-view of the machinery, (with the screws broken off,) and a cog-wheel applied to the centre, to work instead of the chain, as before specified. A, is a handle, that by turning gives motion to the pinion B. C, is another handle, which is used for a quicker motion, and is connected with the axis of the pinion D, and is made to shove in and out of the teeth of the spur-wheel F. E, is another handle, to be occasionally fixed to the axis of the spurwheel F, to be worked as before described; and on the fame axis, is a bevel-pinion G, which acts in a bevel-face wheel H, which is likewise cogged round its edge, and is affixed to the bottom of the fcrew I, which gives motion to the centre cog-wheel K, which gives motion to the other cog-wheel L, which is affixed to the bottom of the other screw M, which causes the nut to descend with the same pressure as above set forth and described. In witness whereof, &c.

XXXI. Remarks on a common Error respecting the Expansion of Water, when converted into Steam. In a Letter to the Editors.

GENTLEMEN,

A MOST flagrant error having been propagated and published, volume after volume, and year after year, for upwards of fifty years past, I beg you will, through the conveyance of the Repertory of Arts, &c. present the public with the following account of its origin and detection.

It has been generally received among those who read, and rely on the veracity and experience of their author, that water, when expanded by heat to that degree of elasticity common to a steamengine, occupies 13000 times its original space; and the author generally quoted on this occasion, is the celebrated Doctor Desaguliers.

I have been much furprifed, that the fact should remain so long uncontroverted; but most of all to find that men of science, who though they would not receive it from verbal report, have notwithstanding read the passage in the doctor's lectures, where the error, (as conspicuous as the paper on which it is printed.) in the second vo-Vol. IX.

lume, page 533, flands thus, in connection with Mr. Beighton's experiment.

"Mr. Beighton's Account of an Experiment which be made on the Fire-Engine, to know what "Quantity of Steam a cubical Inch of Water produces.

"I found by feveral experiments, by a divided " Reelyard on the puppet or fafety valve, on the " top of the boilers at Griff and Wasington, " that when the elasticity of steam was just " one pound avoirdupois on a fquare inch, it " was fufficient to work the engine; and that " about five pints in a minute would feed the boiler, as fast as it confumed in boiling and " fleam for the cylinder fixteen strokes in a mi-" nute. Griff cylinder held 113 gallons of " fleam, every ftroke x by 16 ftrokes in a mi-" nute = 1808 ale gallons; fo five pints of water produced 1808 gallons of steam, 38.2 cubic inches in one pint. Then, 38.2 inches: 1808 gallons :: 1 inch : 47 gallons and three tenths; hence it appears, one cubic inch of water, by " boiling till its elafticity is capable of over-" coming about one-fifteenth of the atmosphere, will make 13 thousand 338 cubic inches of " fteam."

Now observe, he estimates the gallons of steam passing into the cylinder in one minute at 1808, and

and fays that this 1808 gallons of fleam is the produce of 5 pints of water, 38.2 cubic inches to the pint. But, when he comes to state the terms, for the purpose of shewing the expanfion of one inch of water, he makes his first term to be the inches in one pint, instead of the inches in five pints; and, according to him, it stands thus, as 38.2:1808:: 1:47.3; whereas it should be exactly as follows, as 191: 1808:: 1: 9.4+. Now this could not be a typographical error, the terms all agreeing with one another, and the true statement of it makes nine gallons instead of forty-feven, and $9.4 \times 282 = 2650.8$, and 13338 -2650.8 = 10687.2; confequently, the difference is only upwards of ten thousand out of thirteen. according to the experiment: but even the experiment itself must not be admitted as fair and decifive, feeing the cylinder was cooled by the condenfing water at every stroke of the engine, by which much of the steam from the boiler must have been in a state of condensation while it entered the cylinder; fo that Mr. Beighton's experiment, and the Doctor's account of it, ought to go for nothing. I am, &c.

J. C. H.

Pittman's Buildings, City Road, May 21, 1798.

N. B. These lectures have been tranklated into other languages, with the same erroneous statement.

XXXII.

XXXII. Description of an easy Method of clearing Wells, &c. of noxious Air. In a Letter to the Editors, from Mr. T. E. SALMON, of Canterbury.

WITH A PLATE.

THE usual mode of clearing wells of noxious air, by means of forge-bellows and a leather pipe, is certainly very efficacious; but such bellows, &c. are seldom to be procured on the spot, when wanted, and are too weighty and cumbersome to carry about. The sollowing apparatus (invented by me) I have used with great success; and as, with sifty seet of pipe, it weighs only thirty pounds, it may easily be carried to any distance.

Tubes of every kind, being perpendicularly fituated, and having their internal air rarified, cause a current or stream of air to ascend through them. A, B, C, D, E, F, (Plate XII. Fig. 1.) represent six lengths of metal pipe, each eight feet long and two inches diameter; they are all made of tin plate, except the upper one F, which is of copper, the better to bear the heat. G, is a vessel, also made of tin, holding about two gallons, axed fast to the upper pipe F, and having through the sides of it a number of holes, to admit

admit air for the support of the fire. The vessel must be so fixed as to have at least five feet of pipe above its top.

The method of placing it in the well is, by first taking the bottom length A, into the upper end of which enters the lower end of B, and paffing a wire through both, (to prevent their drawing apart again,) as at a, a, in holes made for that purpose: then fill the joint round with oilputty, fo as to render it air-tight. The upper end of each length is wired, to prevent bending; which wiring also forms a receptacle for the putty. Then proceed in the fame manner with the remainder of the pipes, until the bottom one nearly reaches the furface of the water, but not quite. The veffel G is to be supported on two timbers, placed, for that purpose, across the top of the well. H, is a conical cover, to prevent the heat from paffing away too rapidly, and to confine it to the fides of the pipe.

The apparatus being thus fixed, it foon becomes filled with air of the fame quality as that in the well; and, as their power of gravity is the fame, both the external and internal air become flationary, from which there can be no good effect. To put the experiment into execution, fill the kettle G with lighted charcoal, or wood, &c. the copper pipe F being by this means heated, a rarefaction of the internal air takes place, which air, by this means, is deprived of its gravity, and

the external denfe air continuing to prefs with the fame weight as at first into the bottom end of the tube, the equilibrium is deftroyed, and a fuccession of noxious air passes up through the pipe, as through the funnel of a chimney, till the whole quantity is carried off; after which, the pure air, which has in the mean time introduced infelf into the well, begins to pass off by the fame paffage, fo long as the fire is continued.

It may not be amiss here to observe, that although the stream of air passing out of the top of F feems small, yet the effect is great, because that stream confists intirely of the noxious air that is required to be removed; whereas, by the usual method of large bellows and leather pipe, ten gallons of fresh air is perhaps blown into the well, before two gallons of noxious air is displaced; and this probably happens because the atmospheric air is specifically lighter than the noxious air, and afcends through the latter to the top of the well, displacing but a small proportion of it.

The effect feems greater, when the fire-kettle G is placed lower on the pipe, as at D, as by that means more internal air becomes rarified: but it is attended with this disadvantage, that the charcoal-fire renders the air in the well unfit for refpiration. I am, &c. T. E. SALMON.

XXXIII. Conclusion of Mr. Collier's Experiments and Observations on Fermentation, and the Distillation of Ardent Spirit.

(From Page 192.)

II. I SHALL now proceed to the fecond enquiry. Is a greater quantity of fpirit obtained by a free admission, or a total exclusion, of the atmospherical air?

Boerhaave mentions a free admission and emission of the common air, as one of the things necessary to promote fermentation, and his opinion has prevailed to the present day; for M. Chaptal observes, that in order to develop this fermentation, there is required, first, the access of air. Now, if these affertions were true, my account of the operation of fermentation would be effentially wrong; but the following sacts will prove, that so far from a free access of common air being necessary to the spirituous fermentation, it is highly injurious.

I took a bushel of malt, and infused it in a sufficient quantity of water, of 180° of heat, for an hour, and then drew off fix gallons.

10115

With

With water of 200° of heat, I again infused the fame malt another hour, and drew off an equal quantity.

With water of 212° of heat, infused for an hour longer, I drew off fix gallons more.

When the liquor was reduced to fixty degrees of heat, the gravity of each, by my hydrometer, was as follows.

The first infusion had fifty-four degrees of denfity, the second forty-five, and the third twentyfive.

The fix gallons of each infusion were divided into two equal parts; the one for close, the other for open fermentation. These were pitched, with four ounces of yest respectively, the first two parcels at 66° of heat, the second at 60°, and the third at 55°.

The reason of operating on liquors of different densities, and pitching them at different degrees of heat, will be explained hereafter. They are now to be considered as fix different experiments, in support of one sact.

The veffels used for the open fermentation were jars, equally wide at the top as at the bottom, or rather wider. Of those for close fermentation, I have given two drawings (see Plate XII. Figs. 2 and 3.) I prefer having the ends of the tubes immersed in water, as I think it answers the purpose better than common valves. If the vessel be closed

closed round the tube, it is equally air-tight, and the resistance of the water will not be too great for the elasticity of the carbonic acid gas, and other fluids which are raised during the intestine motion; nor is there any fear of the elasticity of the air in the vessel being overcome, by the presfure of the atmospherical air on the surface of the water.

The fermentation was continued till all figns of fermentation had fubfided; the contents of each vessel were then carefully distilled, and their products were as follows.

Table of the Quantity and Strength of the Spirit ob-

Gallons of wort.		Denfity in each experiment.			Heat at		DATE TO STATE OF	unces o		Degrees below proof.

N. B. The gravity of the spirit was ascertained by Dicas's hydrometer, and the density of the worts by my own faccharometer.

Vol. IX. L1 I have

I have frequently repeated the above experiments, varying the denfity and heat of the liquors, as well as the quantity and quality of the ferments; and the spirit produced was always equally in favour of close, in preference to open fermentation. This was also the case, whatever modification of fermentable matter I used, whether molasses, sugar, or potatoes.

I may here observe, on the subject of potatoes, that they never answered the expectation which I had formed from the account given by Dr. Anderson. To procure five quarts of spirit, from feventy pounds of potatoes, appeared very extraordinary; but, from repeated experiments, I am thoroughly fatisfied, that it is not possible, either by the plan proposed by Dr. Anderson, or by any other with which we are acquainted. The farina obtained from feventy pounds of potatoes does not exceed fourteen pounds, (a fact which I have proved by carefully collecting it;) and good molasses, by a well regulated fermentation, will not form more than its bulk of fpirit; from which it will appear very improbable, that ten pints of spirit can be produced from the above quantity of farina *.

^{*} This fact thews us how erroneous the common opinion is, of mixing polatoes with bread, as an object of economy.

In the course of these experiments, I was astonished to find so great a disproportion in the quantity of my liquors, after fermentation. On reslection, it would readily occur, that there would be a diminution of bulk, in that which was fermented in the open vessel; but it was so great, that I at first suspected an error had been committed in dividing the liquors; however, from repeated observation, the difference was so evident, that I made the two sollowing experiments more accurately, to determine the fact.

I took eleven quarts, three ounces and a half, of wort, to which I added four ounces of yest, and sermented it in the close vessel for twelve days; at the end of which time it had lost eight ounces by measure.

An equal quantity of wort and yest was fermented in an open vessel, for the same length of time, and exactly in the same temperature. On measuring this second quantity, I found a diminution of forty ounces.

To determine with certainty whether the liquors remaining in each veffel were equally good, I feparately diffilled the two, leaving out thirty-two ounces of the latter, (which was the difference in quantity,) and the spirit produced from each was exactly alike.

From the two foregoing facts, our information is still more complete; as we not only observe the

great faving in the liquor by close fermentation, but we also see that a diminution of eight ounces had taken place in the close vessel; and we have good grounds for supposing, that it is an actual diminution of the whole of the fermenting mass; from the consideration of which, we shall not be surprised that Chaptal made vinegar from the sluids thrown off by fermentation *.

This part of the subject appeared too interesting to be left without a little farther investigation; as some chemical writers of eminence have stated, that it was pure unadulterated carbonic acid gas which was thrown off by sermentation; others, that it was carbonic acid gas combined with pure alcohol; while many have supposed it to be an union of gas, alcohol, and water †; but none,

* M. I. A. Chaptal communicated to the Academy at Paris (1796) an observation of some curiosity respecting the formation of vinegar. He placed some distilled water above the vinous fluid in fermentation, to impregnate it with carbonic acid. The water, thus impregnated, afforded vinegar; and, at the end of some months, a deposition was made, of a substance in slocks, which was analogous to the sibrous matter of vegetables.

† Lavoisier says, "when this gas is carefully gathered, it is found to be carbonic acid, perfectly pure, and free from admixture with any other species of air or gas." But his translator observes, "that the perfect purity must be taken with some allowance; for it almost always (I believe constantly) contains some alcohol, besides a considerable quantity of aqueous gas, or water, in solution. The latter does not affect its purity, the former does, in some degree."

whose

whose opinion I have seen, have stated it to be what it is, viz. all the elementary principles of the fermenting liquor, highly surcharged with carbonic acid gas.

To determine this more fully, I made the following experiments.

To a fermenting tun, holding about ninety gallons of liquor, I connected two casks with bent tubes, in the manner of Woulse's apparatus. The first cask was sufficiently large to hold all the yest and liquor which ran over the top of the tun, and was left empty to receive them. The second held a quantity of pure water, into which one end of the connecting tube was immersed. The apparatus was adjusted about six hours after the liquor had begun to ferment; and the water was subjected to the action of the fluids which came over in a gaseous state, for fixty hours.

The liquor was divided into three parts, the first of which was immediately distilled, and vielded a small quantity of spirit.

To the fecond I added, at a proper temperature, a little yest, and a new fermentation was excited; by means of which, the quantity of spirit produced was nearly double.

The third was placed in a proper degree of heat to make vinegar, and it is already acidulous.

III. The Effects of different factitious Airs on fermenting Liquors.

It has been before observed, that nothing but saccharine matter can be fermented; and the indefatigable Lavoisier has proved, "that sugar is a true vegetable oxide, with two bases, composed of hydrogen and carbon, brought to the state of an oxide by means of a certain portion of oxygen. Fermentation is the mere separation of its elements into two portions; in which, one part is oxygenated at the expence of the other, so as to form carbonic acid; whilst the other part is disconverted into the combustible substance called alcohol."

It was from a confideration of these circumflances, that I was induced to try what effect an atmosphere of some factitious airs would have on fermentation.

My experiments on this part of the subject have been confined to hydrogen, oxygen, and a mixture of the two. The hydrogen gas was made by decomposing water on iron-filings by heat, not by the sulphuric acid; and the oxygen gas was obtained from the oxide of manganese. The processes were conducted in the following

3

manner: I took three bottles, fimilar to that represented in Plate XII. Fig. 2, into each of which were put thirteen quarts of wort, of forty-five degrees of density; and to each bottle were added four ounces of yest. After the fermentation had begun, I fixed a bag, containing one of the gases, in the stopper of each vessel, by means of a stop-cock and screw. The respective gases were occasionally forced into the bottles, and mixed with the elastic sluids already produced. These operations were continued for eight days, and the bags were replenished with fresh gas every twenty-four hours.

The particular phænomena attending the fermentation of the liquor in each veffel were in no respect important, excepting that the flowers on the surface were not equal to what might have been expected, if no gas had been forced in; that into which the hydrogen gas was thrown was much inferior to the other two.

From observation I was, at first, scarcely able to determine, whether that supplied with a mixture of one part of oxygen and two of hydrogen, or that which was supplied with pure oxygen gas, had the better head; but, from close and repeated inspection, it appeared in favour of the latter.

On distillation, the spirit produced from each was as follows.

By pure oxygen gas By pure hydrogen gas	30 oz.	110°) #
	30	1110
By a mixture of oxygen and		106° ∫ proof.
hydrogen gas	30	1060) 3

Most that we have learned from the three last experiments is, that they are none of them worth repeating as objects of profit; but they serve to confirm our opinion against the admission of air to fermenting liquors. It is true, that none of the above gases were similar to atmospherical air, as that is a mixture of oxygen, azote, and a little carbon *. I did not think it necessary to make any experiments with a mixture of oxygen and azote; for, as there is a column of air constantly rising from fermenting substances, the weight of which is much greater than that of atmospherical air, we cannot suppose that the latter is ever freely admitted, or even admitted at all, in any of the common processes of fermentation.

^{*} One hundred parts of atmospherical air-usually consist of twenty-seven parts of oxygen, and seventy-three of azotic gas; but the pure air is diminished, and carbonic acid formed, according to the number of persons breathing, or the quantity or quality of suel burning, in an atmosphere formed as above.

• My observations on malting, mashing, fermenting, distilling, and rectifying, will be as brief as the nature of the different processes will admit.

Malting, which confifts in developing the faccharine matter by germination, has been denominated, by fome, the faccharine fermentation; but I fee no more propriety in the term, than if it were adopted to express that progress in vegetation which changes mucilage into fœcula.

Margraaf extracted fugar from most vegetables, but it is more completely formed in fome plants than in others, fuch as the Arundo saccharifera, and the Acer saccharinum. Manna is obtained from the leaves of fir, oak, juniper, and the maple-tree. The ash, which is very plenteous in Calabria and Sicily, affords that which is commonly fold both in flakes and in tears; it affords, by distillation, the same products as sugar. The analogy between faccharine matter, mucilages, and gums, is deducible from their containing the radical principle, which, in combination with oxygen, constitutes the oxalic acid: and amylaceous facula is only a flight alteration of mucilage, which may be converted into faccharine matter by germination. Saccharine matter must, therefore, be considered as one of Mm the VOL. IX.

the immediate principles of vegetables, formed by the natural progress of vegetation.

In order to prepare barley for germination, it must be fully saturated with water, which generally requires it to be completely covered for sixty hours. After it is fully saturated, it must be removed; not only for fear of injuring the texture of the grain, but to prevent the water from robbing the barley of its most valuable quality; an occurence which, in some degree, takes place by an ordinary and proper steeping. This is a fact not generally understood; however, it may be easily proved, by subjecting the cold insusion of barley to fermentation, whereby it will produce beer, from which, alcohol may be distilled.

When the barley is taken out of the water, it must be laid in a heap for twenty-four hours: if it were immediately spread thin, it would become dry; no heat would be generated, nor would any vegetation ensue. The grain must be afterwards spread on a cool floor, (if rather moist it would be better,) sprinkled with water, and turned two or three times a day, to give the whole an equal temperature, and keep it sufficiently moist. The appearance of the aqua-spire at the end of the corns, is the usual criterion for taking the malt to the kiln; but I should advise its being urged a little farther, that is to say, I would have the aqua-spire longer, before the grain is removed from the floor.

In drying, or what is generally called curing, malt, the heat should only be continued until all the moisture is dissipated; for the spirit evaporates during the whole process. This sact may be ascertained by drying malt in a retort, to which a receiver is luted containing water; for the water will be found impregnated with spirit, in proportion to the malt dried, and the degree of heat which has been employed.

The method lately adopted, of crushing malt between metal rollers, is certainly preferable to the common process of grinding.

Soft water ought to be invariably used for mashing; and the heat should, in some degree, be varied, according to the different qualities of the malt. But I shall suppose the malt to be good, and then lay down rules for extracting the saccharine matter.

If the water be of too great a degree of heat at the first mashing, it will have a tendency to coagulate the malt, or unite the whole into a pasty mass. On the contrary, if the heat be too low, the liquor will not become transparent, until some degree of acidity takes place. I would, therefore, recommend the following method, as the best calculated to preserve transparency, and to obtain all the fermentable matter.

Infuse the malt in a sufficient quantity of water, of 160° of heat, for an hour; then draw M in 2 off

off the wort, which will be found very finooth, foft, and fweet.

With water of 180° of heat, infuse the same malt another hour, and draw off the liquor as before. Some sweetness will still remain in the malt, for the obtaining of which, it must be again infused in boiling water for another hour. When these three insusans are mixed and reduced to a proper heat, the artificial ferment (yest) may be added.

I have devoted so much of the first part of this effay to the subjects of fermentation, and the application of the faccharometer, that it is not neceffary to enter at large upon them here. The great objects are, to regulate the heat according to the denfity of the liquor, before the yest is added; to keep the fermenting mass in a proper temperature; and to pay strict attention to the construction of the veffels; all of which may be deduced from the former experiments. The close veffels, to which tubes are adjusted and immersed in water, have fome additional advantages, befides those already enumerated: they prevent, in some degree, the temperature of the furrounding atmosphere from affecting the fermentation; and most effectually prevent any acidity from taking place, however long the operation is continued.

It is of confiderable importance to have the liquor clear, and freed from all heterogeneous matter; and, if this has not been done by previous management, the usual method of refining ale or porter ought to be adopted, before the liquor is committed to distillation. A quantity of isinglass dissolved in water, to which a little four beer must be added, has the best and quickest effect.

There is another necessary precaution to be obferved. Care should be taken that the sediment be not disturbed, in removing the liquor, from the vessel in which it has been fermented, to the still. This may be done, either by a tap at a small distance from the bottom of the vessel, or by the introduction of a syphon.

The distillation of the spirit is equally, if not more important than any of the previous processes: for, however good the malt may be, or whatever care may have been taken in the mashing and fermenting, if the distillation be not well conducted, the quantity of spirit will be small, and its quality bad.

To obtain spirit from fermented liquor is the business of the distiller, but to refine and purify it belongs to the rectifier. The second operation is so dependent on the first, that, unless the distillation be carefully conducted, the rectification will be rendered both tedious and difficult.

The art of distilling malt spirit may be reduced to the following principles. 1. To obtain the spirit free from the oil of malt. 2. To raise the vapours in the most economical manner. 3. To condense them as speedily as possible. And, 4, to prevent empyreuma.

The first may be done by mixing a small quantity of sulphuric acid with the wash; and the remaining three by a proper construction of the still, and the necessary care in distillation.

The ftill should be so constructed as to be capable of containing a column of sermentable matter, considerably broader than high, to prevent the liquor at the bottom from being burnt before the upper part is heated. The top should be as wide as the bottom, to give the vapours free and complete liberty to escape; which, by the common construction of stills, are incessantly returned into the boiler, especially as the commencement of the process.

The still recommended by Chaptal is well calculated for the distillation of ardent spirit. The bottom is concave, in order that the fire may be nearly at an equal distance from all the points of its surface: the sides are elevated perpendicularly, in such a manner, that the body exhibits the form of a portion of a cylinder: and this body is covered with a vast capital, surrounded by its refrigeratory. This capital has a groove or channel projecting projecting two inches at its lower part within: the fides have an inclination of fixty-five degrees. The beak of the capital is as high, and as wide, as the capital itself, and insensibly diminishes, till it comes to the worm-pipe. The refrigeratory accompanies the beak or neck, and has a cock at its farther end, which suffers the water to run out, while it is replaced by other cold water, which incessantly flows in from above.

When the water of the refrigeratory begins to be warm, a cock is opened, that it may escape, in proportion as the refrigeratory is supplied with cold water from above.

The distillation of the wash may be kept up, until the quantity limited by act of parliament is obtained; or until the product is no longer inflammable.

Various contrivances have been adopted by the distillers, to prevent the wash from burning in the still. A bundle of clean sticks is sometimes thrown loose into the liquor, to agitate the same during the ebullition. This is more effectually done by a cylinder, sixed in such a manner that it will turn by the action of the steam, and continue a more regular agitation, by means of chains of wood, or metal, connected with the cylinder; but these precautions are scarcely necessary, if the wash has been rendered sufficiently limpid.

Reclification is simple and easy, provided the previous operations have been well managed; but, if an empyreuma has been contracted in the still, or the section oil has been combined with the spirit, then it becomes more difficult. On the contrary, if these have been avoided, nothing more is necessary than to mix the spirit with an equal quantity of pure water, and recommit it to distillation, when it will come over pure.

When the liquor has been burnt in the still, it ought to be kept, for some weeks, in charred veffels; and a quantity of charcoal should be mixed with the spirit and water, previous to the distillation. This will, generally, be found a fufficient remedy for empyreuma, but will not correct the difagreeable flavour communicated by the admixture of the fœtid oil. Many substances have been used for this puspose, none of which, I think, are fully adequate to the end proposed. Filtration has been recommended: but the oil is fo intimately mixed with the spirit, that a confiderable quantity will pass through the filter: the operation is also tedious, and some of the spirit evaporates during the process. Alkaline salts are frequently mixed with the spirit, previous to rectification, fuch as the carbonate of potash, but more frequently the carbonate of foda. They, however, are both liable to confiderable objections, when unaffifted by any other fubstance;

for, although they combine with the oil, and in fome degree prevent its rifing in vapours, yet they communicate an urinous flavour to the fpirit, which is highly injurious. Neutral falts, quick-lime, calcined bones, and chalk, are equally liable to objection, as they do not effectually deprive the fpirit of the oil which it holds in folution, and an improper flavour is also contracted from them.

The method I have adopted, and which is generally attended with the most favourable result, is the following:

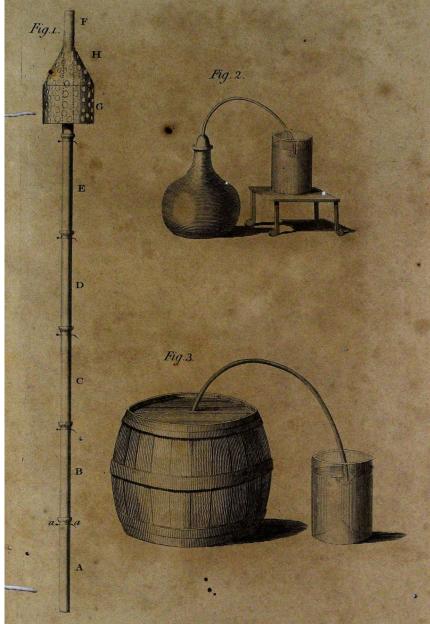

The body of the still is constructed like the former, but the capital is so formed as to admit of a bent tube into the boiler, or rather into a vessel connected with the beak and fixed in the boiler, in such a manner as to form a balneum, to be heated by the liquor in the still. From the top of this vessel an additional beak is continued, similar to that described in the still for the distillation of the wash, and, like it, connected with the worm in the tub.

The liquor intended for purification must be put into the still, with a proportionable quantity of carbonate of soda: and, into the vessel in the still, must be put a quantity of diluted sulphuric acid. After the two capitals are luted, the sire may be lighted, and the vapours will be driven over into the balneum, from which they, will regularly rise with

Vol. IX. N no. the

the heat communicated by the boiling liquor in the still. By this means, the oil will remain combined with the alkali, with which it will form a foap, whilst the bad slavour contracted by the alkali will be totally destroyed; nor will the sulphuric acid be raised in sufficient quantity to injure the taste or quality of the spirit. The same effects may be produced by inverting the order of the process, that is, by mixing the sulphuric acid with the liquor in the still, (about two drams to a gallon,) and putting a strong solution of carbonate of soda into the vessel in the still.

Perfectly pure alcohol may be obtained from the fpirit made by the foregoing rules; but, as the diffillation of alcohol has engaged the attention of many eminent chemifts, I shall not trouble the Society, either with the method of diffilling it, or with its affinities.

XXXIV. Experiments and Observations on the Effest resulting from a Mixture of one Part of Tin with twenty-four Parts of sine or alloyed Gold, when a Plate of the Metal produced by such Mixture is annealed. By M. MATTHEW TILLET.

From the Memotrs of the Academy of Sciences of Paris.

THOUGH it is highly advantageous that scientific men, and artists of known abilities, should make enquiries in those particular branches of work to which they apply themselves, and should publish their observations, yet it sometimes happens that their reputation (in many respects well founded) causes the results they have drawn from their experiments to be too readily adopted; and those experiments, when carefully repeated, are not always found so exact as was supposed. Not that these artists, being well informed, and faithful in the account of their operations, meant that they should be looked upon as decisive; but, by neglecting to consider the facts presented to them,

N no 2

in every point of view, they concluded, too haftily, that those facts were, in all circumstances, such as they appeared to them at first.

Reading the Journal de Physique for September, 1788, I observed a paper intitled, Experiments on mixing Tin with gold *, which I read with great attention, because it is written by a man of great merit and abilities in his profession, namely, Mr. Alchorne, affay-mafter of the English mint, in the Tower of London. As the object of his experiments is interesting to all artists who make use of gold and filver; as his intention was, to remove any fears they might have, respecting the mixture of a certain quantity of tin with fine or alloyed gold; and as it is ftill of confequence that those artists should retain their fears, respecting even the finallest mixture of tin with the gold of different fineness which they are continually melting for use, I thought it right to repeat Mr. Alchorne's experiments; and (while I admit the truth of fome of the facts he has related) to give an account of those circumstances which I have myself observed, and which, if they had not escaped his observation, would have led him to make fome exceptions in the too positive confequences he has deduced from his experiments.

^{*} Mr. Alchorne's paper is printed in our feventh volume, page 26.

Before I give an account of Mr. Alchorne's experiments, and of my own, I think it proper to take notice of the manner in which the editor of the above journal expresses himself, in announcing Mr. Alchorne's paper. He seems convinced that we have, till now, been in an error respecting the essential object of that paper. Consequently that journal, which is deservedly esteemed, and has an extensive circulation, cannot fail to make, in this respect, a strong impression, which ought to be restrained; as it will appear to arise from experiments which were not pursued with sufficient accuracy; and would give an ill-sounded considence to a great number of artists, who work upon the most precious of metals.

It has long, fays the editor, been an acknow-ledged fact, among metallurgifts, that tin mixed with gold, even in the smallest quantity, whether in substance or in vapour, totally destroys the ductility of that precious metal; but Mr. Woulse, Fellow of the Royal Society of London, communicated to that Society, in 1784, a memoir of Mr. Alchorne, assay-master of the English mint, in which he proves, that tin may be mixed with gold, in a moderate quantity, without producing these bad effects. Mr. Alchorne's experiments, he adds, have not been contradicted; yet many of the most respecting the

bad effects of tin, though it appears to be totally unfounded. It is therefore fair to suppose that Mr. Alchorne's memoir is not sufficiently known or attended to, for which reason I think it right to give an abstract of it here, that it may be more generally known.

Mr. Alchorne fays, that he had long had doubts respecting this extraordinary property attributed to tin; and that, an opportunity offering itself, he had made feveral experiments upon the fubject. He mixed twelve ounces of fine gold with different quantities of tin, from fixty grains to half an ounce. These mixtures were flattened under the hammer, paffed through the rollers, and stamped in the money-press, without shewing any figns of brittlenefs. But, when he mixed one ounce of tin with twelve ounces of fine gold, the metal was brittle, and would not bear any of the forementioned operations. He afterwards expoted gold to the fumes or vapour of tin; for which purpose, he put twelve ounces of gold, of twentytwo carats, into a fmall crucible, which he placed in a larger one; and, having furrounded it with tin, he exposed the whole to a considerable degree of heat, during half an hour; but the gold loft none of its ductility. He carried his enquiries still farther; he alloyed the forementioned mixtures with copper and filver, and afterwards added tin to the gold, thus alloyed with different

different proportions of the above metals. But, in all these cases, even when twelve ounces of gold were mixed with half an ounce of tin and two ounces and a half of copper, the metal bore beating and flattening to the thickness of stiff paper, and of being afterwards made into various small trinkets, or drawn into sine wire, with as much facility as the gold usually employed for that purpose.

Mr. Alchorne observes, that the old opinion, adopted by so many authors, probably owes its origin to the arsenick which tin generally contains, as he found that twelve grains of regulus of arsenick rendered gold harsh and brittle; from which he concludes, that tin, like other inserior metals, is injurious to gold, in proportion to the arsenick it contains; and that there is nothing in tin itself, which can deprive that precious metal of its properties, as has been hitherto supposed.

From this abstract of Mr. Alchorne's experiments and observations, it appears that he affirms, that gold, whether pure or alloyed, when melted with tin, in the proportion of one part of the latter to twenty-four parts of gold, forms a metal which possesses sufficient ductility to bear being hammered, flattened to the thickness of striff paper, and drawn into fine wire, with the same facility as that gold which is generally used in commerce.

Although I had no doubt that fin deprived gold of its great ductility, or at least rendered it of harsh and brittle that it could not be reduced into thin plates, and still less be drawn into thin wire, unless it was repeatedly annealed, and managed with a degree of care and attention which its usual ductility does not require; nevertheless, I resolved to repeat Mr. Alchorne's experiments, as well out of respect to so able a man, as that I might be able to supply such facts (if any such should occur) as might have escaped his notice.

In my first experiment, I mixed twenty-four grains of fine gold with one of tin; the tin was taken from an ingot of that metal which contained no arfenick. I wrapped this grain of tin in the gold, which was previously reduced into a thin leaf, and rendered very flexible by annealing. I placed these twenty-five grains upon a piece of charcoal, hollowed out in fuch a manner as to be able to contain them during their fusion. I sprinkled a small quantity of calcined borax over the whole, that it might be more quickly fused, that the two metals might run together, and that the tin, by mixing immediately with the gold, might not have time to be calcined. This mixture, by means of an enameller's lamp, was foon melted, and reduced into a fmall lump, which had loft nothing of its weight. Being then

very carefully flattened under the hammer, it • cracked, and afterwards broke into three pieces, although, as I faid before, I struck it very carefully, and although it was, when it broke, not reduced below a quarter of a line in thickness.

I repeated this first experiment, upon double the quantity of pure gold and of tin, with a similar result: the lump of metal I obtained was brittle, and, like the first, broke under the hammer, although I hammered it with great attention, hoping that I might, notwithstanding its cracks, keep the flattened plate in one piece.

It is hardly necessary to mention, that these experiments were in some measure preparatory, and were merely intended to enable me to guess at the effects I had reason to expect, when I should repeat them on a larger scale, and in a manner more similar to those I meant to examine, in order to establish a comparison between them.

I was unwilling to make use of gold of twenty-four carats, having good reason to fear that it would lose the advantage of being the most ductile of metals, and that I should not be able to restore that property to it, but by the operation of parting; I therefore determined to begin my more decisive experiments upon gold of twenty-two carats, or alloyed with $\frac{1}{24}$ of copper. By so doing, I repeated some of the experiments of Mr.

Vol. IX. O a Alchorne,

Alchorne, from which he had concluded, that tin, when mixed in a certain proportion with gold of this degree of fineness, namely, twenty-two carats, did not deprive the gold of its ductility.

I therefore mixed one gros and twenty-four grains of tin, taken from the ingot which, as I have already mentioned, was free from arfenick, with four ounces of gold, the fineness of which was well known to be of twenty-two carats. These two metals, being reduced into small lumps, were put into a crucible, and exposed to a strong fire, in a forge, with a double pair of bellows. When they appeared to be completely fused, I poured the matter into an ingot-mould, of a fize proportioned to the small quantity of metal I had to pour into it.

TO BE CONCLUDED IN OUR NEXT.

XXXV. Account of an advantageous Method of feparating the Fossil Alkali from Common Salt. By Mr. Westrumb.

From Crell's Chemical Annals.

TWENTY pounds of common falt are to be diffolved in fixty pounds of water *; to which folution are to be added, twenty-five pounds of clean dry potash, the larger lumps of which should be first broken. This lixivium is to be evaporated, by boiling, till the faline pellicle, which is thereby formed on the surface, has several times fallen down, and been replaced by a new one. The vessel in which it is boiled is then to be taken from the fire, and the liquor is to stand till it is almost cold, but not quite, that is, till it is about milk-warm. During the cooling, a great quantity of digestive salt will separate from the liquor, which is then to be strained through stannel, so as to be cleared from all sediment.

* A greater quantity of ingredients may be taken, but it must be observed that this process does not succeed when small quantities are used.

O Q 2

When

When the liquor has frood in a cold place about an hour, or till it is become quite cold, it will be found to have deposited fome more digestive salt, mixed with mineral alkali. The liquor must now be poured off into another vessel, which is to be placed in a cold situation: if the process has been properly conducted, crystals of mineral alkali will soon be formed, which will be almost pure, and in greater abundance than can be obtained by the usual methods.

The faline matter remaining in the strainer confifts of vitriolated tartar and digeftive falt. If the liquor is fuffered to remain upon these extraneous falts till it becomes quite cold, it will, on account of its oily confiftence, be too much incorporated with them; and the quantity remaining on the strainer is too confiderable to be purified from the mineral alkali, in the fame way as the other part; for which reason, after the matter upon the strainer has been a little pressed, let fome warm water be poured upon it, and let it, together with the falt which may have cryftalized after the first decantation, be subjected to the under-mentioned treatment. The digestive falt may be made use of for various purposes, such as making fal-ammoniac, &c.

When the remaining ley has been poured off from the crystalized mineral alkali, it must be again evaporated, and, if much digestive falt should should appear to be formed, it must undergo the same treatment as before; otherwise it may be immediately suffered to grow cold, and the digestive salt which is deposited may be laid aside, to be afterwards purified.

When the alkaline falt is crystalized, the remaining ley is to be again evaporated, that all the falt may be separated from it. If any ley then remains, it may be set aside for the next operation, or it may be put into a glass vessel, and placed, to evaporate, in the heat of a stove, till no more digestive salt is precipitated, after which the alkali may be suffered to crystalize in the cold.

By this process, the abovementioned quantity of common salt generally affords twenty-five pounds of impure mineral alkali; and the whole of this operation may very easily be finished in fix or seven days.

The digestive falt obtained in the last operation, and the alkali itself, are now to be purified in the following manner.

The first, that is, the digestive salt, is to be dissolved, by boiling in water; the solution is then to be evaporated till about half of it is consumed, and afterwards placed in the cold. The digestive salt will crystalize first, upon which will be deposited the mineral alkali, in large crystals, so that it may be easily separated. By evaporating

porating the remaining liquor a fecond time, the purification of the digeffive falt may be completely finished. If any ley containing mineral alkali should still be left, it may be purified with that which remains at last.

The mineral alkali is to be purified by diffolving it in an equal quantity of water, and letting the liquor stand some days in a cold place. If it contains a large quantity of digestive salt, this salt will appear when the liquor (the first crystalization having been separated from it) is evaporated a second time; at which time may be added that alkali which was obtained in the former purisication of digestive salt. If the alkali contains but little digestive salt, this salt will not appear till the third evaporation of the liquor, by which time, if the operation has been carefully and skilfully conducted, almost all the alkali will have been separated.

By the method here described, I have almost always obtained twenty pounds of pure mineral alkali, in large transparent crystals, besides one pound and a half, less pure. The whole process may be finished in twelve or fourteen days, or even in less time, when the different leys are operated upon at the same time, instead of taking them exactly in the order above described.

XXXVI. Lift of Patents for Inventions, &c.

(Continued from Page 216.)

ABRAHAM BOSQUET, of Stangate, in the parish of Lambeth, in the county of Surry, Esquire, formerly of Sandymount, in the county of Dublin, and late one of his Majesty's Commissaries of the Musters; for a method, by the application of which, his Majesty's navy, and all trading veffels, may derive durability, soundness, standardness, and many other advantages. Dated June 8, 1708.

JOHN HAZLEDINE, of Bridgenorth, in the county of Salop, Iron-founder; for a method of reducing and forming large pigs and pieces of iron, copper, brafs, and other metals, into bars, plates, and hoops, of different breadths, fizes, and shapes. Dated June 14, 1798.

RICHARD SHANNON, of Charlotte-street, in the parish of St. Pancras, Middlesex, Doctor of Physic; for a method of improving the process of fermentation, by which, porter, beer, ale, malt,

malt, molasses, wash, wine, cyder, and all other faccharine and fermentable fluids, may be conducted with certainty and success through the various processes of fermentation, in any state of the weather, &c. Dated June 19, 1798.

Patrick Rooney Nugent, late acting furveyor general of lands for the islands of Cape Breton, in North America, but now of London, Esquire; for mathematical instruments, whereby the latitude and longitude, variation and inclination of the magnetic needle, at sea, and on shore, may be obtained in a more general, masterly, and perfect manner, than hath hitherto been done. Dated June 27, 1798.

John Pearce, the younger, of Wolverhampton, in the county of Stafford, Millwright; for confincting, making, working, and using, combs and machines for combing of wool, in a better manner than any now in use. Dated June 30, 1798.

DAY GUNBY, of Cross-street, Hatton Garden, Middlesex, Carpenter; for weights, bolts, and springs, for improving all kinds of writing and reading desks, tables, chairs, stools, tambour frames, library-steps, bedsteads, and various other articles. Dated July 6, 1798.

REPERTORY

OF

ARTS AND MANUFACTURES.

NUMBER LIII.

Printed by John Nichols, Red-Lion-Passage, Fleet-Street, London.

XXXVII. Specification of the Patent granted to Mr. Jonathan Hornblower, of the Borough of Penryn, in the County of Cornwall, Engineer; for his new-invented Machine or Engine for raifing Water, and for various other useful Purposes in Arts and Manufactures, by means of Steam and otherwise.

WITH TWO PLATES.

Dated June 8, 1798.

TO all to whom these presents shall come, &c. Now know YE, that in compliance with the said proviso, and in pursuance of the said statute, I the said Jonathan Hornblower do declare, that the following is a particular description of the Vol. IX.

P. p. nature

nature of my faid invention, both in respect to its principles, and also the way and manner in c which the same is performed and rendered practicably useful; that is to fay, First, in respect to principles. I admit the fteam from the fteamvessels or boilers, into certain other vessels, fo particularly contrived and disposed as to produce an immediate circular motion round an axis, and thereby communicate a rotary motion also, to other parts that may be appended to, or connected with, the machine; without the intervention of that wheel work, and other complicated machinery, which has hitherto been found neceffary, where motions that are rotative are produced by means of fuch as are rectilinear and interchangeable.

Scondly. I cause the steam to operate on certain moveable parts within the aforesaid vessels, in such a manner that they occasionally, and alternately, serve the purpose of abutments to the force of the steam, in one direction, when admitted between them; but, in a contrary direction, are permitted freely to revolve in perpetual succession, the one after the other.

Thirdly. Those particular parts of the machine which I cause to serve as abutments to each other, also serve the purpose of moveable diaphragms or partitions, each having an apartment within it-

felf; and, by means of which partitions, I establish separate apartments within the body of those vessels which receive the steam from the boiler. Into some of these there is a constant accession of steam, and others have open and uninterrupted communication with cold water.

Lastly. From the practical application of the foregoing principles, as hereinafter particularly fet forth, I obviate all those inconveniencies attendant on such steam engines as are retarded in their operations, from vis inertie, as often as the direction of their motions are reversed; and consequently require both a smaller quantity of such, and machines of smaller dimensions, for the necessary work to be performed.

And, in order for the better comprehension and understanding how the aforesaid principles may be reduced to practical use, I do hereby farther declare, that although I vary my modes of construction, as a difference in circumstances may offer, to produce the same effect, and obtain the main purpose intended, yet I principally adhere to the following method, as being sully answerable to what is required, and as best calculated to be understood from a description of the same; that is to say,

First. The vessel in which the steam operates confists of a hollow cylinder, composed of

two unequal parts, the smaller section of which is screwed off and on, for the purpose of rectifying and repairing the internal structure. These parts are cast separate, and then screwed together, firm and close, by means of proper margins or slanches for the purpose; and in that state the cylinder is bored true from one end to the other. At each end of this cylinder, slanches are also cast, for the purpose of screwing on two lids, which are faced true on their sides next to the body of the cylinder, and the whole will then form a figure somewhat resembling a drum.

Secondly. The lids of this veffel are perforated in the centres, for the reception of two metalline tubes, which meet in the centre of the drum, and thereby form a hollow axis, through one end of which the steam enters the body of the drum, and through the other makes its exit to the condensing water. On these two tubes are fixed two moveable parts of the machine, which I call diaphragms, the nature and construction of which will be best understood by attending to the annexed figures. (See Plates XIII and XIV.) A, Z, Fig. 6, are the two tubes, which pass through the central openings in the lids of the drum, meeting each other at B. a, b, c, d, are the interior limits of those tubes, on the in-

fide of the drum, which are confiderably larger • than at A, Z, in their diameters; the use of which is, that there shall be a proper cavity at e, f, g, b, to receive a packing of tow and greafe, or any other materials answering the purpole, between that particular part and the end of the drum; and also that the frames of the diaphragms C, C, may have the firmer holding to the hollow axles or tubes at D, D, leaving the parts of the diaphragm pendant at i, k. The dotted lines shew the interior limits of the drum, when the diaphragms are in their places; between which and the extremities of the diaphragms there is a proper rabbet, to receive the packing, and as well also between the pendant part of the diaphragms and the central hollow tube about which it revolves. This rabbet is formed by means of plates of metal, screwed on to the frame of the diaphragms, having their edges nearly in contact with the inner furface of the drum, and will be found acceffible to repair or renew the packing, when the pannel which conftitutes a part of the drum is removed. The parts e, f, g, b, may also be repaired at the fame time, by means of removing two fcrews at each end of the hollow tube. (See Fig. 3.) The diaphragms (which are here standing in opposite directions) may therefore freely revolve the one after the other, or one

may move, whilft the other remains flationary. The tubes to which they are attached will have their concentricity preferved, by means of the folid axle within the hollow one at E, (Fig. 6,) which is fixed to the end of the tube Z, and paffes closely through a hole in the end of the tube A, till it reaches the extremity at Y; where, by means of a fecond collar, its central position is critically maintained. The two diaphragms are hollow within, and hold communication with the cavities of their respective tubes which compose the hollow axis; and these communications are made by oblong openings, where the diaphragms and tubes are connected together at D, D.

Fig. 3, represents the diaphragms and tubes enclosed within the drum, the diaphragms being compleated by having their plates screwed on; in these plates are fixed two valves G, G. Opposite to which are two others, one in each diaphragm, so corresponding that at the opening of one the other is closed, and vice versa. These valves are balanced, and held on trunnions, so that, in every situation of the diaphragms, they may uniformly obey the impulse by which they are opened and shut; the manner in which that is effected is as follows. The two diaphragms widen towards their extremities, in the manner of radii, (see Fig. 5,) and may therefore be brought

into fufficient contact to force open the valves, by means of certain prominent parts in them for that purpose. It should here be noted, that the efforts by which the valves are caused to open take nothing from the power of the machine, because the impulses are reciprocally communicated from one diaphragm to the other, in one common direction.

Thirdly. To explain the manner in which the diaphragms are wrought upon, when in their proper place, let Fig. 5 reprefent one end of the hollow cylinder or drum which furrounds them, one of the lids being taken away. The central circles exhibit the ends of the hollow tubes which have already been explained in Fig. 6. The two diverging parts are the ends of the two diaphragms, which, as before mentioned, are packed with tow and greafe, or other packing, and are furnished with valves; now these diaphragms being hollow within, if we confider one of them to be constantly supplied with steam, by means of the hollow tube to which it is connected, and the other continually holding communication with the condenfing water, the confequence will be, when fream is admitted through a valve into the leffer apartment of the drum, and another valve open from the empty diaphragms into the larger apartment, that the diaphragms will recede from each

each other, with all the force of the fleam between them; but if, by proper prevention, they can move only in one direction, it is plain that the one will remain stationary, till overtaken by the other; their junction will then shift the valves into contrary positions, by means of the prominent parts in them for that purpose, and the apartment before filled with fleam inflantly becoming empty, the diaphragm, which was before stationary, now becomes active, and the momentum of the former may, in effect, be confidered as transferred to the latter. There being therefore, in these parts of the machine, a continual motion, by rapidly fucceeding each other in a circular direction, their respective axles on which they turn, and which communicate motion to other machinery without the drum. are influenced in the fame manner, agreeable to the main principles herein primarily fet forth.

Fourthly. In order that the steam shall have a power of turning the diaphragms only in one direction, let Fig. 4 represent one of the lids of the drum, having the side that is faced true on the opposite direction to that exhibited in the drawing; in this is a circular channel GG, and a projecting ring P, which serves as a perpetual fulcrum to support the two levers C, D, that occasionally

casionally revolve in the channel, and act as detents. The outer boundary of the channel also acts as a fulcrum to the extremity of the two levers at their thick ends; fo that, when they are acted upon, from their connection with the axles turning them to the right hand, by means of a ftrong collar E, there will be no impediment to their freely revolving in the circular channel; but, when the axles strain upon the small ends of the levers in a contrary direction, they inflantly become fixed fo firmly, between the two boundaries of the channel, as effectually to refift the whole force of the machine. And, in order that these levers may operate with the greatest advantage. an exact counter-part is provided in the false lids D, E, Fig. 3, which fcrew on to the drum: and the ring P, Fig. 4, may be supposed to be a part of these lids; by which means, the links which connect the levers and the collars together partly disappear, to shew that both the channel in the inner lid of the drum, and that in the false lid, are partly occupied by the thickness of the lever. To provide against the least retrograde motion whatever, when the levers may be partly worn from friction, they are furnished with springs between them and the outer extremity of the channel, fo that the two bearing points may at least touch their respective fulcrums. Fifthly.

Qq

Vol. IX.

Fifthly. By an inspection of the part S, Fig. 3, which I call the tympanum, it will be perceived that there are proper channels, a,b, for the reception of four levers, similar to those at Fig. 4, which will there also act as detents; two being connected with the hollow axle I, and the other two fixed on the folid axle w; so that, as the axles are turned in succession, by the diaphragms within the drum, the tympanum may be continually carried on by one or the other of the detents; and, being firmly connected with the shaft R, both it and the tympanum are uniformly turned, with the whole power of the diaphragms, as long as the steam is admitted between them.

Sixthly. The water that enters the machine for condensing the steam, is extracted by a pump, which may also be made to extricate any air that by accident, or otherwise, may enter the machine; or a separate pump may be made use of for the purpose, after the manner that is commonly practised.

Seventhly. Where a confiderable altitude of water can be obtained, I lay afide the use of a pump, and the machine is then calculated in every respect for being wrought by means of water passing through it.

Parts in the drawing remaining to be explained. A, Fig. 3, the brafs which receives the end

of the hollow axle, through which the fleam makes its exit to the condenfing water. This brass is adjusted to maintain the central position of the pivot, by means of the screw at L, when the machine stands erect; but, when horizontally, the screw is fixed at c. B, is the opening leading to the pump; that at C opens to the boiler. o o o o, the space between the false and inner lids of the drum, for receiving the detents, which are collared upon a part of the hollow axle, left octagon in those places. F, a passage for the steam to enter into the proper diaphragm, paffing between the inner extremity of the hollow axle and the outer extremity of the folid one. Here the due proportion of fream that enters is adjusted by means of a collar of brafs, with rings on it, which is made to move forward and backward, by means of a pinion interfecting the projecting rings, which rings ferve as teeth, and this pinion is moved on the outfide. (See Fig. 1.) At d, Fig. 3, is a hole from the hollow axle into the folid one, in order that, when the brafs collar does not admit fteam enough to keep out the atmosphere at the stuffing collar, a fufficient quantity may enter by that way, for that purpose, into the apartment o, Fig. 6, where it will meet the stuffing in the apartment p, and keep out the air; though it may partly pass into the diaphragm, where the folid Qq2

folid axle nearly fills the hollow one, at q. The ftuffing round this folid axle, is fupplied through two oblong openings at e, Fig. 3, covered over by means of a clasping gland V; this clasp also ferves to retain the fluffing round the hollow axle at X, which may be repaired, either by taking off the clasp, or through two oblong openings in the iron stuffing box at y: The air cannot enter the machine at the stuffing round the hollow axle, because the strength of the steam on the infide is uniformly the fame with that in the boiler, or nearly fo. The end of the folid axle has its pivot inferted into the main shaft, where the tympanum is fixed; and the braffes on which the main shaft turns are adjusted by screws, at any time, for maintaining the central position of both the folid and hollow axles within the body of the machine. When used to produce alternate motions, on the main shaft, Fig. 2, is fixed a fly-wheel, at B, in order to regulate the unequal action and re-action, between the rectilinear motion of the pumpwork and the circular direction of the diaphragms. In witness whereof, &c.

EXPLANATION OF THE FIGURES.

XXXVIII. Specification of the Patent granted to Mr. Charles Tennant, Bleacher of Darnley, near Glafgow; for his Method of using calcareous Earth, and the Earths Strontites and Barytes, instead of alkaline Substances, for neutralizing the Muriatic Acid Gas used in bleaching; and for employing those Earths in the other Parts of the Process of bleaching, instead of alkaline Substances.

Dated January 23, 1798.

O all to whom these presents shall come, &c. Now know YE, that in compliance with the faid provifo, I the faid Charles Tennant do hereby declare, that my faid invention is described in manner following; that is to fay, this invention confifts in a new method of employing calcareous earth, either uncalcined or in the state of ewick-lime, for which may be fubflituted the earth properly called barytes, or that known by the name of strontites, or the earth magnesia, either in their carbonated or calcined forms, though more advantageously in the latter. As all these earths are equally applicable in this invention, it will be fufficient only to specify the way of employing calcareous earth; it being the most abundant

abundant and eafiest to be procured, will therefore be generally preferred. The calcareous earth, (in whatever state of its varieties it is intended to be used, and which may be employed almost indiscriminately, although the purer the better,) being calcined and reduced to the state of quicklime, in order to be employed to the greatest advantage, should be passed through a fine wirefieve; which will be eafily accomplished, if the lime has been previously flaked with a little water. Next, a proportion of this powdered lime is to be put into the receiver, or veffel in use by the bleacher for preparing his bleaching liquor, and where hitherto a folution of alkaline falts, fuch as pot and pearl ashes, &c. has been in general used, to catch and retain the oxygenated muriatic acid gas; my construction, or form, of which receiver, or of the apparatus in general, I do not condescend upon, that which is at present in general use answering perfectly well. When the ingredients put into the retort, to procure this gas, (whether manganese and common murianis acid; or manganese, common salt, and oil of vitriol; or indeed any other materials capable of yielding it;) begin to give it out, then it is neceffary to keep the liquor in the receiver, which contains the quick-lime, in as confrant a state of agitation as poslible, fo that the fine particles of the lime be diffused throughout the whole of the

the liquor in the receiver, for on this the fuccels of the operation depends. I disclaim any right to the discovery of the simple chemical solution of lime in water, commonly called lime-water, for retaining and fixing the oxygenated muriatic acid gas, it having been long known that limewater had fome effect in this way; but, from the quantity of lime that is foluble in water being fo exceedingly fmall, (only about a feven hundredth part of its weight,) no great benefit was found to be derived from it; whereas, by this process of keeping the lime in a state of mechanical suspenfion, floating through every part of the fluid in the receiver, it greedily abforbs the oxygenated muriatic acid gas; forming inftantly, as it does fo, a foluble compound, which possesses, in an equal or even superior degree, the qualities of the bleaching liquor ufually made by the help of an alkaline lixivium, having the very fame whitening and detergent powers, as well as that most valuable one, of not discharging dyed colours, but, on the contrary, preferving and enlivening them. I cannot take upon me to state the specific quantity of lime necessary to be put into the receiver, for making a given quantity of bleaching liquor, as that must depend entirely upon the ftrength and other qualities the liquor is wanted to poffes; however, by use of the following proportion of ingredients, a very excellent, and comparatively Vol. IX. Rr.

· 306 Patent for using calcareous Earth, &c.

paratively very cheap liquor will be obtained, to what can be procured by using an alkaline ley, ftrong enough to absorb and retain the oxygenated muriatic acid gas produceable from the same materials. In a receiver capable of containing one hundred and forty gallons, wine meafure, diffolve thirty pounds of common falt, which appears useful only in giving an additional degree of specific gravity to the water, and by that means making it easier to keep the lime, to be afterwards added, fufpended; and for which common falt, any other fubstance possessing a fimilar power may be used, and which is itself by no means effentially necessary; when this falt is doffolved, add fixty pounds of finely-powdered quick-lime; and into the retort of the apparatus put thirty pounds of manganese, mixed up with thirty pounds of common falt; upon which, pour thirty pounds of oil of vitriol, previously diluted with its bulk of water, and the usual precaution of luting the veffel well, &c. taken. When the gas begins to appear, the agitation of the lime and water in the receiver must commence; which should be continued, by means of a wooden paddle or rake, of almost any construction, without intermission, until the materials are wrought off, (after employing heat as ufual,) and will not yield any more oxygenated muriatic acid gas. Then the whole should be allowed to remain at

rest for two or three hours; when the clear liquor in the receiver may be drawn off for use, and will be found to possess all the qualities before afcribed to it. Although I have mentioned the above proportions of materials, for making bleaching liquor by my difcovery, I think it necessary to declare, that thefe are not the only ones that will be found to answer, as they may be varied with good effects, almost ad infinitum, according to the purpose to which the liquor is to be applied. Alfo, that the spirit of my discovery confifts in my having found out that the calcareous earth, and that called barytes, and that called strontites, either in their carbonated or calcined states, by being kept in a state of mechanical sufpenfion in water, or other watery fluid, are capable of uniting with the oxygenated muriatic acid gas, and forming a compound that can be used with great efficacy in bleaching; and also, that these earths, thus mechanically suspended, may be used advantageously in the other parts of the process of bleaching, where alkaline falts have been hitherto employed. From the far greater degree of folubility which the earths barytes and strontites possess, in comparison to lime, I have discovered that a chemical folution of them may be used, with very great effect, in neutralizing the oxygenated muriatic acid, and in other proceffes of bleaching, instead of alkaline substances; and Rro 2

· 308 Patent for using calcareous Earth, &c:

and that either the mechanical or chemical fufpension of these earths may be employed with great success, although the former will be attended with more than the latter. In witness whereof, &c.

The following Information respecting the above Method of bleaching, was sent us by Mr. Couper, Surgeon, of Glasgow, who is connected with the Patentee.

The liquor, prepared as fet forth in the specification, has now been fairly tried by many of the principal bleachers in England, Scotland, and Ireland, and is regularly used by them in the course of their business. The saving in ashes, to such bleachers, is very great; and the privilege of the patent has been fold to them for a sum equal to a single half year's saving of ashes derived from using it. It has been found equally useful in bleaching linen and cotton. To the sinen and cotton printers, it promises to be of singular advantage, as well in saving of ashes, as in shortening the time for preparing their goods for printing.

The bleachers who now use this process, as well as the patentee, are convinced that it will foon be univerfally adopted in every process for whitening

whitening vegetable fubftances, and will become a great national faving, not only by faving the afhes commonly used in making bleaching liquor, but by diminishing the necessity of using such quantities in boiling.

The principal point of attention, in preparing it, is to obtain a compleat diffusion of the lime through the water, that is, a mechanical fuspenfion of it in the water, in opposition to a chemical folution of it, as formerly tried, in form of lime-water. By this means, the oxygenated muriatic acid gas is absorbed with ease, and meets with a fufficient quantity of lime to produce a strong folution of oxygenated muriate of lime, without any uncombined oxygenated muriatic acid, a thing which could not be effected by ufing lime-water alone.

Different forms of veffels have been used for containing the lime and water: either cylindrical, containing an upright shaft, with horizontal arms, and turned round by means of a winch; or veifels of an oblong shape, where the agitation is effected by the motion of rakes or plungers, of obvious and eafy conftruction. To infure the more conftant motion of these parts of the apparatus, they have, by many of the bleachers, been connected with the wheel of their plash-mill, or other moving machinery necessary in their operations.

XXXIX. Specification of the Patent granted to Mr. Henry Johnson, of London, Gentleman; for a certain Water-Proof Compound, and a Vegetable Liquid; which Liquid is for the Purpose of bleaching, whitening, and cleansing, Woollens, Linens, Cottons, and other Articles; and also for preparing Stuffs or Cloths made of Woollen, Linen, Cotton, or Silk, in order, by the Application of the aforesaid Water-Proof Compound, to render them impenetrable to Wet, and more elastic and durable, when made into Garments, &c. for Wear; which Stuffs I call Hydrolaines.

Dated July 7, 1797.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said Henry Johnson do hereby describe and ascertain the nature of my said invention, and in what manner the same is to be performed, as follows; that is to say, First, to make the said vegetable liquid, I the said Henry Johnson either take horse-chesnuts, or orange-peels and

and kernels, which are found thrown away after · squeezing, or the offals and gall of fish, or either of them, according to the place where they are to be had. I boil them for four or five hours, and then leave them to cool and fettle for a few days; or else I add eight quarts of water to every pound of a calcined fubftance called British barilla, which remains for diffolution two or three days. To any or either of these decoctions, (drawn off fine,) I add one pound of kelp or wood ashes, refined and purified (by a method well known) to be equal to pearl-ash, or else pearl-ashes themselves, to every twenty quarts of any of the above liquids; and, after well mixing and remaining for twenty-four hours, I then flake a fuperior fort of lime therein, called Ryegate lime, in order to give it the caloric, and precipitate the charcoal of the ashes, and to modify its causticity. To this prepared lime, (drawn off fine,) I add the following preparation, viz. to every quart of fish, linfeed, or any other oil, I put forty quarts of water, and boil it with half an ounce of falt of forrel, falt of fugar, or rectified falt of tartar, which incorporates the oil and the water; and this, after fettling for twelve hours, I draw off fine; and, to every twelve quarts of the above prepared liquid, I add one quart of this last incorporated oil and water; and this, when fettled, I call blanching lixivium.

· Secondly, as to the water-proof compound, I proceed as follows: after the linen, woollen, cotton, or filk stuffs, or cloths, hats, or leather, are prepared by the above-defcribed blanching lixivium, I stretch them in a frame; and, having diffolved caoutchouc or India rubber in spirit of turpentine, (the fmell of which is taken off by oil of wormwood and spirit of wine, in equal quantities,) the caoutchouc having become a varnish, I spread it (with a large piece of undiffolved caoutchouc, inftead of a fponge or brufh) upon the wrong fide of the prepared stuff, cloth, or leather, and then fift over it any coloured cloth, or filk, or worsted, or coney or other wool cut fine, in the fame manner as flock-paper is made; and, being left to dry for a day or two, this flock, by its adhesion to the caoutchouc, is equal to any lining. In witness whereof, &c.

XL. Account of the Manner in which Rice is made into Bread, or boiled for the Table, in Carolina. In a Letter to the Editors, from Mr. John Drayton, of Charles Town.

South Carolina, Charles Town, July 22, 1793.

GENTLEMEN,

I FIND an account given, in one of your numbers *, of the American mode of making ricebread. It appears to be more complicated and tedious than that used in Carolina; and, as rice is used here in an extensive degree, I hope you will pardon my intrusion, when I endeavour to describe the method by which we adapt this grain to the purposes of subfishence.

The first step towards preparing the cleaned rice for bread, is to wash it thoroughly in water. This is done by putting it into any vessel, and pouring water upon it; then stirring it, and changing the water, until it is sufficiently cleansed. The water is then poured off entirely, and the rice placed, in an inclined position, to drain. Aster being sufficiently drained, it is put, while damp, into a mortar, and beaten to powder; it is

^{*} See our fifth volume, page 350.

then taken out, and made completely dry; and is finally passed through a common kitchen hair-fieve. The reason why it is thrown damp into the mortar is, the pulverising is thereby much assisted, and the labour rendered more easy.

The rice-flour is kneaded up with a small proportion of Indian corn meal, boiled into a confistence which we term bomony; or it is sometimes mixed with a sew boiled potatoes; to which a small quantity of leaven and salt is added. When the fermentation has been sufficiently excited, the dough is put into pans, and placed in the oven, to be baked. By this process, a light wholesome bread is made, not only pleasing to the eye, but agreeable to the taste.

Our manner of boiling rice, for the use of our tables, is simple and expeditious. About half an hour before dinner-time, the rice, being sirst washed, is thrown into a small pot of boiling water, and then boiled, until the grains are softened and nearly done. The water is then poured off; and the rice, covered up in the pot, remains to simmer, or more properly to steam, over a slow fire, until it becomes dressed to any given degree of moisture or dryness. The degree which we prefer, is just when the glutinous quality of the rice ends, and before the desiccation begins.

I am, &c. John Drayton.

XLI. Additional Observations on making a Thermometer for measuring the higher Degrees of Heat. By Mr. Josiah Wedgwood, F. R.S. Potter to her Majesty.

WITH A PLATE.

From the Philosophical Transactions of the Royal Society of London.

IN my first paper on making a thermometer for measuring the higher degrees of heat *, I communicated every thing that experience had then taught me, respecting both the construction and use of this thermometer; but more extensive practice has since convinced me, that other managements and precautions are necessary, in order to bring it to the perfection it is capable of receiving; for, pieces made of the same clay, and exactly of the same dimensions, have been found to differ in the degree of their diminution by fire, in consequence of some circumstances in the mode of their formation, at that time unheeded, and very difficult to be developed.

Of

^{*} This paper is inferted in our fixth volume, page 255.

Of the two ways proposed for forming them, the mould and the press, the former was made choice of, as being, for general use, the most commodious. The fost clay was pressed into a square mould, with the singers; and the pieces, when dry, were pared down on two opposite sides, by means of a paring gage made for that purpose, so as to pass exactly to o°, at the entrance of the converging canal of the measuring gage.

But the pieces thus formed have been found liable, in passing through strong fire, to receive a little alteration in their figure, which produces an uncertainty with respect to their subsequent measurement. The two sides, instead of continuing flat, become concave; the edges, both at top and bottom, projecting beyond the middle part, fometimes very confiderably, as at a and b, Fig. 1, (Plate XV.) where AB reprefents a perpendicular fection of an unburnt piece, and a b a like fection of the same piece, after it has undergone a heat of 160 degrees. This irregularity in the form, which is fenfible only after passing through the high degrees of fire, was observed in some of the early experiments, but was not then looked upon as being productive of any

On more attentively examining this matter, it appeared, that when the clay is preffed into a mould, the furface in contact with the mould acquires

acquires a more compact texture than the inner part of the mass; that this compactness restrains, in some degree, its diminution in the fire, and therefore, that when this furface, or less diminishable crust, is pared off from the two sides only, the piece may be confidered as having its upper and lower strata (A A and B B, Fig. 1.) composed of a less diminishable matter than the intermediate part; the necessary consequence of which structure will be such a figure as we find the pieces to assume; for, if any stratum in the mass shrinks less than the rest, the extremities of that ftratum must be left proportionably prominent. That this was the true cause of the inequality, I was convinced, by firing fome pieces unadjusted, with all their furfaces entire, as they came from the mould; for these pieces after, paffing through the fame strong fires with the preceding, continued flat, with the angles regularly sharp, and without the least fensible prominence in any part.

Some of the moulds employed for this use were made of plaster, a material more convenient for the workman than metal, as the pieces part more freely from it, but which contributed greatly to increase the above-mentioned irregularity; for the plaster, by absorbing a portion of the water from the clay contiguous to it, renders the surface, at the same time, even at the instant of contact.

contact, much more confishent, and consequently more difficult to press into the angles of the mould; so that the outsides of these pieces were not only more compressed, but formed of clay of a different temper from the inner parts, being much drier or firmer; a circumstance which, as will appear hereaster, restrains still more their diminution in the fire.

The moulds were therefore laid afide, and the press adopted in their stead, for, as the soft clay, pressed in a cylindrical vessel, gives way and escapes through an aperture made for that purpose, (by which means it is formed into long rods,) the sides of the pieces cannot be supposed to receive so great a degree of compressure against the sides of the aperture through which it is delivered, in this operation, as it does against the sides of the mould, by which it is confined till every part has born a pressure sufficient to force the clay into every angle, which is much greater than even a workman would imagine, till he comes to try the experiment himself.

But, with this change, some new difficulties arose; for, pieces pressed through the same aperture, and from the same press-full of clay, and adjusted, when dry, to the same point in the gage, were sound, after passing together through the same strong sires, to differ in their dimensions from one another, in some instances, more than any of the preceding.

Having hitherto paid no particular attention myself to the mere manual labour of pressing the clay, I determined, upon this event, to go through that and every other operation, however simple and seemingly insignificant, with my own hands.

In doing this, I observed, that the power necessary for forcing the clay through an aperture which bore but a small proportion to the diameter of the mass of clay in the press, was so great as to squeeze out, along with the clay that first passed through, a considerable portion of the water that belonged to the rest. From this over proportion of water, in the composition of the first pieces, they were soft and spongy, and the succeeding ones more and more compact, till at length the clay proved so stiff as scarcely to be forced through at all.

Clay containing different proportions of water, is well known to diminish differently in drying; but, it was not imagined that, when dry, there would be any difference in its subsequent diminutions by fire. Experiments, however, multiplied in a variety of circumstances, shewed decifively, what the pieces formed in the mould had given grounds to suspect, that those formed of the softest clay, and which had undergone the least pressure, diminished most in burning; and that the diminution is uniformly less

and less, in proportion to the greater degree of preffure or compactness.

The knowledge of the cause of the irregularity fuggested a remedy. I lessened the width of the prefs very much, fo as to bring the diameter of the mass of clay, and that of the aperture through which it is delivered, to a nearer proportion with one another. A much less degree of force being now fufficient, the pieces or rods were proportionably more uniform, though there was still a sensible difference, in consistence, between those which were first and last pressed out from the fame mass of clay. The intermediate ones, within a certain diftance from the two extremes, corresponded very nearly with one another; so that, by rejecting a fufficient number of the first and last, and using the intermediate ones only, the inequality may be confidered as almost annihilated.

I nevertheless ftill found that, in strong fire, the edges became a little prominent, though not so much as before. I was aware that these pieces must partake, in some degree, of the imperfection of those made in the mould; having their surfaces rendered, by their friction against the sides of the aperture, more compact than the inner part. But I suspected that something might depend also upon the form, and accordingly made many trials for ascertaining the form that might be least liable to this irregularity. The angles only

were bevelled off; the fides were rounded; the pieces were rounded all over; made of ovals and other curves; and both the longest and shortest dimensions were used as the extent to be meafured. The general refult was, that the hearer they came to a circular figure, the lefs inequality they contracted in the fire; and, by making them entirely circular, the imperfection appeared to be obviated altogether; cylindric pieces bearing the strongest fires, without the least appearance of prominence or inequality in any part of their furface. I have therefore chosen this last form, leaving only one narrow flat fide, (a b, Fig. 2.) as a bottom for the pieces to rest upon, and to distinguish the position in which they are to be measured in the gage.

I have endeavoured, at the fame time, to obviate whatever inaccuracy the inequality of compactness may be capable of producing, by so adjusting the aperture through which the rods are pressed, and on which their figure and dimensions depend, as to superfede the use of the paring gage altogether; that the whole surface may remain of the same uniform compactness which it received in the press. And, as it is scarcely practicable, in any mode of forming soft clay, to have all the pieces precisely of the same dimensions after drying, I do not reject those which come within two or three degrees of the standard;

Vol. IX. Tt but,

322 Additional Observations on a Thermometer

but, initead of injuring the furface by paring of rubbing, I mark on the ends, the degrees which they respectively exceed, or fall short; which degrees are accordingly to be substracted, or added, in all observations of heat made with those pieces. Strictly speaking, an allowance ought to be made also, for the proportional diminution upon this excess or deficiency itself; but the allowances for three degrees would not, at the melting heats of copper, silver, or gold, amount to more than a seventh part of a degree; and, at the most extreme point of heat that I have been able to attain, when the piece has diminished $\frac{1}{6}\frac{6}{6}\frac{6}{6}$, or about one-fourth of its whole thickness, it comes only to four-sifths of a degree.

It may be proper to take notice of an irregularity in the apparent diminutions of the pieces, which was fometimes observed to happen from another cause, viz. their bending a little in strong fire, so as to be prevented from going so far in the gage as they would have done if they had continued perfectly straight. But, as this takes place only in pieces of considerable length, and as they derive no advantage of any kind from that length, the remedy is too obvious to need being here mentioned.

Another fallacious appearance arose, not from any impersection in the pieces themselves, but from a deception with respect to the heat in which the

comparison of them had been made. In one period of the course of my experiments, I employed, for firing them, a small shallow cylindrical vessels, (Fig. 3,) setting the pieces on end, close together, on its bottom, and placing it in the middle of the suel, in a common air-furnace, with care to keep the fire as equal all round it as possible. It was expected that all the pieces would receive an equal heat; and, as they were found, after the operation, to differ in their dimensions, sometimes considerably, from one another, these differences proved a source of much perplexity, till it was discovered, that the pieces had really unergone unequal degrees of heat.

In the paper on the comparison of this thermometer with Fahrenheit's *, I have taken notice of the great difficulty of obtaining, in small furnaces, a perfectly equal heat, even through the extent occupied by a few of these little pieces; and how different the heat may be in different parts of one vessel, we may be satisfied by an easy experiment, viz. setting a cylindrical rod of clay, of the length of eight or ten inches, upright m the middle of a crucible, and urging it with strong fire, in a common small surnace. The rod will be found very differently diminished, at different parts of its height; and, if its height be

^{*} See our feventh volume, page 173, and 239.

fufficient to reach some way above the fuel, nearly the whole range of the thermometric scale may be produced in one rod: an ocular proof, not only of the diverfity of heat within a fmall compass, but likewise of the peculiar sensibility of this thermometer; every part of the mass expressing distinctly the degree of heat which it has itfelf felt. It will be proper, in this experiment, to have a tube fixed in the bottom of the crucible, for keeping the rod fteady, as at Fig. 4. By this means, the heat of my air-furnace renders a rod of the thermometric clay tapering, from about four parts in diameter at top to three at bottom; which are nearly the proportions between the width of the piece when unburnt, or but just ignited, and when it has fuffered a heat of 160 degrees

To the foregoing fources of inequality in the pieces, one more may be added, viz. fmall cavities or air-bubbles, accidentally inclosed, which fometimes happened in the earlier experiments. In order to prevent these, particular attention is now paid by the workmen to what we call bandling or sapping the clay, an operation by which its different parts are intermixed, and the mass rendered of an uniform temper throughout. The workman takes a lump of the clay in his hands, perhaps of two pounds weight, and, breaking it in two in the middle, lays one part upon the other,

and presses them flat again, repeating this forty or fifty times, or perhaps oftener. Now, confidering the pieces at first as two dissimilar masses, with any number of air-bubbles inclosed, each of these pieces being by the first doubling divided into two, by the next into four, by the third into eight, and fo on in geometrical progression, each of the original masses will be divided by the fiftieth repetition, into upwards of eleven thousand millions of millions of invisible laminæ; invisible, because the lump of clay would, long before the last doubling, be of one uniform colour, though at first one half of it had been black and the other white. If therefore no air be inclosed between the pieces, at the times of their being put together in this process, all the air which might have been in the mass before would certainly be driven out; and, to avoid as much as possible the introduction of any fresh portions of air, the two separated pieces are each time made fmooth, and a little convex, on the furfaces that are to be brought together.

By due attention to the circumstances above stated, any single quantity of clay may be made up into thermometer-pieces, that shall differ very little, if any thing at all, from one another.

But a new difficulty now arose, more embarrassing than any of the former; that of procuring fresh supplies of clay, of the same thermometric quality

quality with the first. The quantity of the clay which, after trial of many others, I had made choice of, was finall; but the particular spot it was taken from being known, and having purchased the little estate in which it was raised, I had not a doubt of obtaining more of the fame, when it should be wanted; for clays in general, when raifed from an equal depth, in the fame stratum, and near the same place, are found to possess the same properties, with respect to ductility in the hands of the workman, a disposition to assume by fire a porcelain or vitreous texture, fingly or in composition, and all other qualities relative to their use in pottery. In this, however, I was deceived; for, when a fresh supply was wanted to complete my experiments, though I had fome taken from a pit joining to the first, and at the fame depth, it was found to diminish differently from the former parcel. I then had fome raifed from different parts of the fame field and bed, and at different depths; and in various other places in Cornwall, from the fpot where this species of clay is first met with to the land's end. But all these clays differed so much from the first, in the quantity of their diminution by fire, and most of them likewise from each other, that I despaired of being ever able to find one that would correspond with it, or any natural clays that could be obtained twice of exactly the fame

same thermometric properties, how fimilar soever in other respects.

Upon a review of the numerous comparisons which I have made of these new clays, in different degrees of heat, from the commencement of redness up to intense fire, the most striking differences of the greatest part of them, from the old, seemed to originate in the lower stages of heat; and, of those which were got from the neighbourhood of the old, the variations from it, in the higher stages, seemed, for the most part, to be only consequences of those differences in the lower ones.

I have mentioned, in my first paper, that the original thermometer-pieces had their bulk enlarged a little on the approach of ignition; but that, by the time they became vifibly red-hot throughout, they were reduced to their former dimensions again, and at this moment the thermometric diminution begins. The new clays had their bulk enlarged in a much greater proportion, and the enlargement was of much longer continuance. Some of them required a heat of fifteen degrees, to destroy the increase which ignition had produced in their bulk, and bring them back to their original dimensions: after this period, most of them diminished pretty regularly, and uniformly with the old, being nearly fo many degrees behind it, in all the fucceeding stages of heat.

heat, as they required to bring them back from the enlarged state.

I have mentioned also, in my former paper, that a quantity of air is extricated from the clay, most rapidly at the period in which the angmentation of bulk takes place; and that the augmentation was probably owing to this air forcing the particles of the clay a little afunder, previous to the instant of its escape. It was therefore prefumed, that the greater extension of these new clays might be owing, either to a greater quantity, or stronger adhesion, of this combined air; and, as clay kept moist for a length of time, in certain circumstances, undergoes a process seemingly analogous to fermentation, it was hoped that, by such a process, part of its combined air might be detached.

But experiments made on this idea have proved, that these clays, kept moist for a twelve-month,—kept for a considerable length of time in a heat just below visible redness,—boiled in water for many hours,—alternately and repeatedly moistened and dried,—fuffer no alteration in their thermometric properties, and continue to differ from the standard clay, just as much as they did at first.

Some of these new clays differed from the old in a property still more effential, and by which I was much more disconcerted; for, though they continued

continued diminishing with tolerable regularity, keeping only fome degrees behind it, up to a -certain period of heat, about that in which caftiron melts; yet many of the pieces, urged with a heat known to be greater than that, were found not to be diminished so much as those which had fuffered only that lower heat. Farther experiments shewed, that after diminishing to a certain point, they begin, upon an increase of the heat beyond that point, to fwell again : and, as this effect is constant in certain days, and begins earliest in those that are most vitrescible, and as clays are found to fwell upon the approach of vitrification, I look upon this fecond enlargement of bulk, however inconfiderable, as a fure indication of the clay or composition having gone beyond the true porcelain state, and of a dispofition taking place towards vitrification; which stage is always, as far as my experience reaches, attended with a new extrication of air; and, in fome infrances, this air being unable to make its escape from the tenacious mass that envelopes it, the burnt clay is thereby fo much encreased in bulk as to fwim on water, like very light wood. The degree of heat, therefore, at which this enlargement begins, may be confidered as a criterion of the degree of vitrescibility of the compofition; which points out a new use of this thermometer, enabling us to afcertain the degree of Vol. IX. vitrescibility

vitrescibility of bodies that cannot actually be vitrified by any fires which our furnaces are capable of producing.

All my refearches among the natural clays proving fruitless, and the experiments having shewn, that all those which could sufficiently refift vitrification diminished too little in the fire, I endeavoured to find a body possessed of the opposite property, that is, diminishing too much, and, by a mixture of these two, to produce the medium diminution required. As I could not find any natural substance possessed of that property, which would not at the fame time render the compound too vitrescible, I was obliged to have recourse to some artificial preparation; and, as the earth of alum is the pure argillaceous earth, to which all clays owe their property of diminution in the fire possessing that property in a greater or less degree, according to the quantity of alumearth in their composition, I mixed some of this earth with the clay, and found it to answer my wishes completely, both in procuring the necesfary degree of diminution, and increasing its unvitrescibility. So little is this compound disposed to vitrification, that the greatest heat I could give it, that of 160°, did not even bring it to a porcelain texture, but left it ftill bibulous; and, as it does not arrive at the porcelain state, in this fire, there can be no danger of its approaching

too near to the vitrescent, in any heat that we can produce in a furnace.

In order to obtain the exact medium required, I took one of the best of the clays I had procured from Cornwall, and mixed it with different proportions of the alum-earth, till the composition was found, on repeated trials, to agree with the original in all degrees of heat. This coincidence was not indeed essential; but, as many degrees of heat were already before the public, measured by thermometer-pieces made of the first clay, and as the correspondence of the first with Fahrenheit's scale had likewise been in some measure ascertained, it was desirable that the same degrees of heat should continue to be expressed by the same numbers.

The alum-earth is prepared for this purpose by dissolving the alum in water, precipitating with a folution of fixed alkali, and washing the earth repeatedly, with large quantities of boiling water. When the earth has settled, the water above it is let off by cocks in the sides of the hogsheads; and, when the vessels are filled up with fresh water, care is taken to stir up the earth from the bottom, and mix it thoroughly with the liquor. I find it most convenient to use the earth undried, in its gelatinous state, as, in this state, it unites easily and perfectly with the clay; whereas, when the alum-earth has concreted into dry masses,

great labour is necessary to mix them uniformly together.

I have tried several different parcels of English alum, from the fame and from different manufactories, and found no material difference in the quantity of earth it contains *. Nor indeed would it be of any confequence, if there was a difference in this respect; as the proportion of alum-earth necessary for different clays, and even for different parcels of the fame clay, can only be afcertained by repeated trials, adding fucceffive quantities of the earth till the defired effect is found to be produced. Ten hundred weight of the Cornwall porcelain-clay which I have now in use, required all the earth that was afforded by five hundred weight of alum.

It is material in this place to observe, that the earth of alum is extremely tenacious of water, infomuch that, though apparently dry, the water and air amount to near as much as the pure earth, and are not to be completely driven out,

without

^{*} A difference in the quantity of earth may arise from different proportions of Glauber's falt and vitriolated tartar, of which I have found quantities very confiderable, but nearly alike, in all the English alum I have examined. These salts are doubtless formed by the kelp ashes employed in the preparation of the alum. They are discovered by calcining the dried alum with charcoal-powder, which decomposes the alum only, leaving the two other falts intermixed with the alum-earth, whence they may be extracted by water.

without a full red heat. When divided by the admixture of other earthy bodies, it parts with its water eafier indeed than before; but a mixture containing fo much of it as the thermometric composition does, is far more retentive of water than common clay, and requires to be kept for fome time in a heat equal to that of boiling water, before it is to be confidered as dry, that is, before the adjustment of the pieces in the gage. If they are adjusted when only apparently dry, or of fuch a degree of dryness as they can be brought to by a heat that the hand can bear, the heat of boiling water will diminish them two or three degrees; and, the greatest part of what they have thus been deprived of, they gradually recover again on being exposed to the atmosphere, fo that the adjustment must be made immediately after the boiling heat.

By the fame expedient to which I have thus been obliged to have recourse, for procuring to the porcelain-clay of Cornwall the standard degree of diminution and refistance to fire, the fame qualities may probably be communicated to any other clay that is tolerably pure from calcareous earth and iron; fo that the thermometer clay is no longer to be confidered as the produce of any particular fpot, (which was the principal inconvenience originally imagined to attend it,) but may be procured and prepared in all parts of the world, where good common clay and alum are to be found; and correspondent thermometers may consequently be constructed, without any standard to copy from. For, if a converging canal be formed, of any convenient length, with the widths at the two ends in the proportion of 5 to 3, with the fides perfectly ftraight, and divided into 240 equal parts, numbering the divifions from the wider end*; and, if a clay be obtained of fuch quality that, when formed, in the manner already mentioned, into pieces of fuch fize as to enter to o in the gage or canal, these pieces shall just begin to diminish, or go a little farther in the canal, by a heat vifibly red; go to 27, by the heat in which copper melts; to about 90, by the welding heat of iron; to about 160, by the greatest heat that can be produced with coaked pit-coal, in a well-conftructed common air-furnace, about eight inches square, still continuing bibulous, fo as to flick to the tongue; fuch gages, and pieces of fuch clay, fo adjusted, will always compose correspondent thermometers.

Having mentioned oecafionally feveral alternate periods of dilatation and contraction in clay, it may be proper to state, and bring into one view,

^{*} Or the divisions on the side may be continued to 300; and, in that case, instead of the widths of the two ends being in proportion to the odd numbers 5 and 3, the one will be just double to the other.

the whole fuccession of changes which I have obferved in this curious material; as otherwife they might create some confusion in the minds of those who have not had occasion to think attentively on this subject, and lead them to ask, how a body so variable, and liable to fuch opposite changes from different degrees of heat, can yet be a just meafure of those degrees.

The changes which take place in all the natural clays that have come under my examination,

- 1. The first is, the shrinking of the moist clay, in drying, from the mere loss of its water. The purer the clay is, the more water it requires to foften it, and the more it diminishes in bulk, by the lofs of that water.
- 2. The dry clay, gradually heated, preferves its bulk unvaried, up to the approach of ignition. At this period, it is enlarged a little; probably, as already observed, from its combined air endeavouring to escape.
- 3. When this air has made its escape, the clay begins to diminish, or to lose the bulk it had before acquired; and returns back, fooner or later, to the fame dimensions which it was of when dry. It is at this point, that the thermometric diminution
- 4. From this point, the clay continues to dimiwish more and more, in proportion as the heat is encreased.

encreased. This I call the thermometric stage of diminution; it is of greater or less extent, terminating at different periods of heat, according to the nature of the clay. In the flandard thermometer clay, it commences with visible ignition, and continues to (and doubtless far beyond) the extreme heats of our furnaces; an interval confifting of 160 degrees of the scale. In others, it begins 4, 6, and in some even 15, of those degrees later, and terminates also much fooner: and in fome, its whole extent is not above 20 of the fame degrees. Throughout the greatest part of this stage, the clays are found to retain their property. of flicking to the tongue and imbibing water: between this bibulous state and the vitrescent, there is an intermediate one, diffinguished by the name of porcelain; and, to the higher term of this porcelain flate, the stage of thermometric diminution feems to continue.

5. When the clay has passed the porcelain state, it begins to be enlarged again; a symptom of the vitrescent stage being commenced; and in this period it swells more or less, according to the nature of its composition.

6. By farther heat, the fwelled mass, becoming fluid, subsides; is converted into glass or slag; and contracted into less volume than the clay occupied in any of its preceding states.

Īţ

It is plain, therefore, that clay can be a meafure of heat no farther than from ignition, or that point beyond ignition where the third stage terminates, to the beginning of the vitrescent stage; and that, as the three first changes are completely paffed before the clay is applied to thermometric purpofes, being ftrictly no other than preparatory processes, the thermometer-pieces, whatever clay they may be made of, (provided it is sufficiently unvitrescible,) are to be confidered as possessing only the fourth stage. But a fingular property of the composition of clay and alum-earth remains to be mentioned, viz. that it has really no other than this one stage: it suffers no enlargement of its bulk at ignition, or in any other period, but proceeds in one uninterrupted course of diminution, from the foft state in which the pieces are formed, up to the extreme fires of our furnaces. Though the diminution, however, is uninterrupted, it is at the fame time fo inconfiderable at the beginning, from the heat of boiling water (at which the pieces are adjusted) up to ignition, that the same point of visible redness is taken for the commencement of the scale, in this, as in the original clay, without any fenfible error, or variation in their progrefs.

I am inclined to believe, though experiments have not yet enabled me to speak with certainty on this point, that the same cause which enlarges

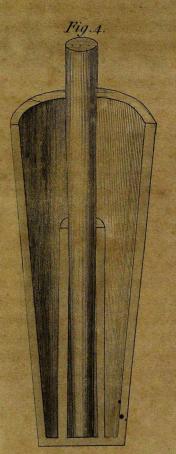

Vol. IX. Xx the

the natural clays, on their first exposure to the fire, operates also in this composition, but in a much lower degree; and that, while the natural clays have their whole mass distended by the efforts of the air in forcing its passage, the composition is only restrained in its diminution, or prevented from diminishing so fast as it otherwise would do, and as it is found to do in the subsequent part of its course, after the air has escaped from it.

As the composition of clay and alum-earth is far more tenacious of water than the clay itself, and was found, after being dried by the heat of boiling water, to yield, by distillation in a retort, above three times as much aqueous fluid as the original thermometric clay did, it feems probable, that a part of this water, retained to the approach of ignition, and in a state of chemical combination, may facilitate the passage of the air; ferving as a vehicle to convey it off, through interstices not permeable to air alone, and confequently enabling it to escape, without doing that violence to the mass which the natural clays suftain from the expulsion of their air after the water has been detached from it; for the experiments of Dr. Priestley have shewn, that vessels, even of burnt clay, are permeable to air, when they have imbibed water into their fubstance, though not at all fo in a dry state.

XLII. Observations on the Construction of Ships.

By Sir George Shee, Bart. M. R. I. A.

From the Transactions of the Royal Irish Academy.

I WAS first led to suspect that the construction of fhips built in Europe admitted of improvement, by observing, that vessels employed on the river Ganges, and on different coasts of India, carried great burdens, in proportion to their dimenfions; and, on examining them, I found that, however widely they differed from each other in appearance, great expansion was common to them all. The veffels of the Ganges, it is true, being constructed to move at times in shallow water, were not, I found, well calculated to fail near the wind; but this defect I knew could be remedied; and it was fufficient for my purpose to ascertain the fact, that, when heavily laden, they could be moved with greater velocity than veffels on the European construction, of the fame burden, could be by an equal impulse, with ballast only on board.

The

The opinion I had thus formed was strengthened, in the course of a voyage I made from Bengal to England. Observing that the Rodney, a company's ship, which I was on board of, appeared longer, and failed faster, than other Indiamen, I made enquiry as to her construction; and was informed that, on laying her keel, fhe had been intended for a ship of much more confiderable burden, but that, owing to a temporary fcarcity of timber, all her dimensions had been abridged, except that her length was fuffered to remain, and confequently to exceed, by fome feet, the usual proportion. On our arrival in the channel, with the wind about a point before the beam, we overtook a fleet of West Indiamen, and we out-failed them with fuch facility, that they might almost have been supposed water-logged.

These observations, with many others, led me to bestow more attention than I had before paid, to an examination of the mechanical principles applied to the building of ships; and, the more I extended my enquiries, the more I was convinced that their construction was desective. Had, however, my conclusions not been strength ened by previous observation, I should not have thought them worthy attention; for I am mysel so much an Insidel in theoretic systems in general, that I offer considerable violence to my mind whenever I subscribe to their truth, unless confirmed

firmed by fomething like experimental proof; and I should not therefore expect from others much attention to remarks merely theoretic.

A glaring defect in fhips employed in transporting merchandize is, that they draw too much water, or are conftructed too deep. It is well known that every floating body propelled, muft, in its progress, displace a body of water equal in weight to itself, and equal in bulk to the part fituated below the furface; and that this operation must be repeated, as often as the body moved advances a diffance equal to its own length. Now, as the line of least refistance from the water displaced is upwards, it follows, that the force necessary for its removal must be great, in proportion to the diffance of any part of it from the furface; and hence arifes the facility with which veffels drawing little water are moved, even when the burden they carry is confiderable.

Another defect in merchant veffels is, that they are too short. The progress of a ship that wants length is impeded by perpetual ascent and descent, even in water but moderately agitated; while one that has it proceeds with little more than direct motion. But this is not the only objection to want of length. The tendency of the upper sails of a ship is, not only to propel horizontally, but in a very considerable degree to press down the head and elevate the stern, as will appear

appear evident, when it is confidered that the mast is acted upon as a lever; the upper deck is the fulcrum, and the parts above and below it the two arms. Now the action of the wind that fills the upper fails is nearly upon the point of the long arm, and the degree of refisfance to the depressing force so caused, is determined by the length of the line from one extreme horizontal point of the ship to the other; when therefore this line is fhort, in proportion to the height of the maft, the effect is not only evident in a high or ripling sea, with the wind fair and strong, but, even in smooth water, the vessel, particularly if fmall, proceeds with evident deviation from the horizontal position which her hull is intended to preferve, as well when in motion as at anchor: and, by this means, the points of direct refultance are multiplied, as the height of the frothy wave at the bows of fuch veffels in their progrefs, or the disproportion of that wave to their velocity, hape, and fize, evidently shews.

A third defect, not lefs ftriking than thefe, is that the veffels I mention are too narrow. A few feet of length add little to the fize of fhips, as to burden, but a fingle foot in breadth increases prodigiously their capacity to fustain weight. The shape of merchant veffels in general may be faid, from its tendency, to resemble an extended wedge, perpendicularly placed; every ton additional

additional weight preffes them down confiderably, and, from the practice of overloading them) in order to proportion their burden to their failing, charges, and original cost, they commonly proceed on a voyage almost buried in the water. To this circumstance alone, the loss of numbers of them may be ascribed; for a captain must be positive that the danger is excessive, before he can hold himself justified in attempting to lighten the ship; and, in situations the most perilous, this is often found impracticable.

The remedy for these desects is easily stated, but the practicability of applying it requires explanation; as inveterate prejudices in the minds of ship-builders are to be opposed, and strong prepossessions, in the minds even of men of science, who have thought mechanics deserving their attention, to be combated.

To give ships great horizontal expansion, in proportion to their depth, which I conceive effential to the perfection of their form, the construction of their hulls, in other respects, must undergo a change. The bow and the sides are, or rather ought to be, constructed upon principles directly opposite. The one is to break through the water; the other to resist all force that gives the body of the vessel a disposition to lee-way. The perfection of the former is, to have as few points of direct resistance as possible; that of the latter,

latter, it would feem, to prefent as many; must it not then, to an unprejudiced observer, appear extraordinary, that both parts should be composed of segments of circles; scarcely a superficial square foot of the largest ship's side, below the water-mark, lying perpendicular to horizontal pressure? The keel, in fact, with some small extent of plain immediately above it, springing from the bottom, are trusted to for resistance; but these are, in most cases, insufficient; sew vesses, except frigates, and others of extraordinary length, being found to fail well upon a wind.

An argument, univerfally used by seamen and ship-builders, in support of the present construction as to depth, is, that what they technically call "a gripe of the water below the power of the surge" is essential in preventing vessels from being driven to leeward. As this argument strikes directly at the root of any improved system founded on expansion, it is necessary that it should not remain unanswered.

A gripe below the influence of the furge, if it means any thing, implies refiftance to the force of waves beating against a ship's side. Now, supposing this resistance possible, the first high sea that should strike her on the beam, in a gale of wind, would inevitably either overset or destroy her, by forcing in her side; the security therefore

of ships, in numberless cases that constantly occur, depends on their yielding to the force of the waves. Admitting, however, for argument sake, that, in storms, the dexterity of seamen may prevent a ship from being exposed to the violence of the sea upon her broadside, let us see how, in moderate weather, the deep gripe can operate.

Waves, I believe, are not thought to run very high, when they rife from fix to ten feet above the water-level, that is, from twelve to twenty above the trough of the fea; there are few ships whose draught of water exceeds twenty; is it not evident then, that vessels, through all gradations of fize, even on their present construction, are in general completely exposed to the power of the furge?

But, as experiment fuperfedes arguments, any person in whose mind doubt exists upon this subject, may fatisfy himself by viewing a small cutter, when failing upon a wind, in company with large ships; or by observing a wherry, which draws still less water, working to windward: nay, even a ship's long-boat, the most flat of all sea vessels, may serve to convince him, that he may dismiss those doubts, without running much risk of falling into error, and fatisfy him that, provided a vessel have hold of the water proportionate to her size, it is of little moment whether the gripe be near to, or remote from, the surface.

TO BE CONCLUDED, IN OUR NEXT.

VOL. IX.

Y v XLIII.

XLIII. Conclusion of M. Tillet's Experiments and Observations on the Effect produced by mixing Tin with Gold.

(From Page 282.)

THE ingot I obtained from this fusion, had fcarcely loft any thing of the weight of the two metals I had employed; a circumstance which ferved to prove, that the tin had completely incorporated with the four ounces of gold with which I had mixed it. But, when I attempted to bend the ingot, which was about fix inches in length, and not above two or three lines in thicknefs, I remarked that, contrary to the usual nature of gold of twenty-two carats, it was rigid, and would have required a pretty confiderable effort to bend it and strengthen it again, in the manner which might have been eafily done, if there had been no tin in its composition. I immediately faw that this harshness intimated a diminution of its ductility, and that the introduction of a fubstance which was foreign to the gold, and

of a nature incapable of maintaining its cohefion, was the cause of this defect in flexibility; which defect could only be attributed to the tin, because copper alone, when mixed with fine gold, (though it gives the gold a degree of hardness and confistence which it does not naturally possess,) takes from it scarcely any of its ductility.

After this first observation of the state of the ingot I had obtained from my experiment, I proceeded to a more decifive trial, viz. that of forging the ingot, and examining what would happen to it when beat with the hammer, and particularly with the sharp part of it, in such a manner that the metal might be extended, and by that means undergo the strongest trial. I did not observe that by this operation (which was continued until the ingot was reduced to about two thirds of its original thickness) the edges of the bar were at all cracked, or that it yet shewed any great figns of brittleness; but, as I feared that this accident would happen, if I continued to hammer it for a longer time, I cut off that part of the bar which I had beat out with the edge of the hammer, and afterwards placed it between lighted charcoal, in order that, by being moderately annealed, it might be reftored to the degree of malleability it possessed before it had been hammered.

Y y 2

But, when I went to take it out of the fire, where it had undergone no greater degree of heat than that of a cherry-red, I found it divided longitudinally into two pieces. After letting them cool, I hammered them again. They were extended with tolerable eafe, but with fome cracks at the edges. I was not fatisfied as to what I had farther to expect, and therefore annealed only one of the two pieces I had twice hammered, and kept the other piece in its hardened state, in order to pass it, in that state, through the rollers. The piece I annealed, which might be about the thickness of a shilling, broke in the fire, though the heat was very moderate; it also bent and twisted itself, in such a way as to shew that it was strongly contracted in various directions, and feemed inclined to break and divide itself into fmall pieces, fimilar to those which were already separated from it.

This circumstance led me to suspect, that the assess upon which I had annealed the plate of gold which had broke in pieces, might contain some portions of it, and I was not mistaken; for I obtained from these assess, by carefully washing them, three or sour small pieces of the plate, which the live coals with which it was covered had concealed from my sight.

I have already faid, that I referred one of the two pieces of that portion of the ingot which I

had forged a fecond time, and that I had kept it in the hardened state in which it came from under the hammer. I could not doubt, after the effect I have just related, that by attempting to anneal this piece, before I flattened it, I should meet with the same accident I had just witnessed, that is to say, that it would break as soon as it became red-hot, however careful I might be to expose it only to a moderate fire.

I therefore determined to extend it still farther, by passing it between the rollers, and to flatten it very gradually, that the fracture, if any should happen, might be owing chiefly to the harshness of the metal, and not to its being made to undergo a violent compression.

By these precautions, I contrived, notwithstanding the harshness of the metal, to extend the piece to double its length, and to reduce it to the thickness of stiff paper. It is however true, that the sides of the plate were cracked all along, so as very much to resemble the teeth of a saw. But this circumstance will not be thought surprising, with respect to gold, which, though alloyed only with copper, has not, whatever may be the cause thereof, its usual ductility, particularly when we endeavour to reduce it very thin, without annealing it repeatedly, as the metal grows hard.

It might be supposed, by reflecting upon the experiment I have just related, that the breaking of the gold plates perhaps arose from the two metals having been imperfectly fused, or from their having been unequally mixed; and it appeared to me that, in confequence of this idea, which might not be ill-founded, it would be proper to melt the ingot again, with all the pieces which were broken from it, and to take particular care that, after being well mixed together, it should be in complete sussion when poured out. As foon as the metal was completely fufed, I threw a small quantity of calcined borax upon it, that the furface might be cleared, and that all foreign matter might be carried to the fides. The use of this quantity of borax, could produce no other effect than a greater degree of foftness in the metal, and confequently less risk that it would break, when it should be extended under the hammer.

All the precautions I took in melting this ingot were useles. When I forged one of the ends, it was, like the former, lengthened very easily, without any perceptible crack; but, when this end of the ingot was afterwards reduced very thin, and exposed to the annealing heat, it broke into several pieces, the longest of which was so twisted, that I have no doubt that it would also

have broke, if the heat had been more ftrong, or longer continued.

Although the experiment of which I have just given the refult, and in which one part of tin was mixed with twenty-four parts of gold of twenty-two carats, might fairly be confidered as fufficient proof that this alloy deprives gold of a great part of its ductility, and exposes it, in annealing, to an accident which artists would hardly be able to avoid, on account of their being obliged to anneal continually the gold upon which they work, in order to restore to it that malleability which it has loft under the hammer; nevertheless, however unwilling I might be to deprive the gold of its ductility, which could only be restored to it by a fresh parting process, I thought I ought to repeat the experiment with gold of twenty-four carats, and in such quantity that my experiment might be compared with that made by Mr. Alchorne, from which principally he drew his conclusion.

I therefore, in this new experiment, made use of fix ounces of fine gold, and two gros of tin. The first mentioned metal was divided into a great number of pieces, and I inclosed the two gros of tin in two leaves, formed of a part of the fix ounces of gold, which were so thin and so slexible, ater being annealed, that they completely enveloped the two gros of tin. After putting

putting a part of the gold at the bottom of a finall crucible, I placed the tin, wrapped in the gold leaves, upon it; over which I put the remaining part of the gold.

When the whole of the two metals was in complete fusion, and had been well mixed, I poured the matter hastily into the same ingot-mould I had before used; and I obtained an ingot which was a little longer, and cleaner, than the two former ones.

As foon as it was cold, I forged one of the ends, with the edge of the hammer. It was lengthened, without any appearance of a crack: and, when it was reduced to about the thickness of a line, I cut it off, that I might treat it feparately. After moderate annealing, it was still entire; and, excepting a few cracks, it paffed through the rollers without breaking. But, as I was fearful that it might break, on account of its harshness, if I continued to flatten it, I slightly annealed it once more. It had hardly acquired, between the charcoal, the red colour of a cherry, before it broke into five or fix pieces: fome of which were flightly bent or twifted; others were quite flat, as they came from the rollers. Amongst the annealed pieces belonging to that end of the ingot which I was at work upon, there was one rather long, which was only a little twifted, and which I undertook to laminate afresh; refolving

folving to reduce it very thin, without annealing it at all. It acquired at least double its first length without breaking, and, although the two edges of this plate were cracked, the principal part or body was entire: it was elastic, and might have been supposed to have been formed out of an ingot of common gold, in which no tin was contained, but which did not posses its usual ductility.

It refults from the experiments I have just related, that if a small quantity of tin, even of the purest kind, is added to gold, whether fine or alloyed, and the two metals are perfectly fused together, the gold, in confequence of this mixture, acquires a certain degree of harshness and rigidity, and lofes fomewhat of the colour by which it is diffinguished. It may indeed, by proper management, be extended, to a certain degree, under the hammer, or (which is preferable) between the rollers; but, as it cannot bear annealing, without great risk of breaking, it loses, by this defect, the great advantage it otherwife possesses, of being restored, after it has been hardened, to its original state of ductility. It is only by means of great care in the use of the hammer, and by frequent annealing, that the artists who work in gold and filver, contrive to finish and perfect their works without cracks, or without being obliged to have recourse to the use of folder, to repair those defects which excessive hardness from hammering would be apt to occafion. How careful therefore ought goldsmiths and jewellers to be, to prevent tin from being brought into their workshops, and to avoid using any kind of gold which appears liable to break, or even to twist, while annealing! The expence of refining such gold, would be an object of less consequence to them, than the additional time which would be consumed in managing gold adulterated with tin; if indeed they did ultimately succeed in working it, and were not forced, after a great deal of trouble, to abandon a piece of work they had nearly finished.

I have no doubt that Mr. Alchorne, if he had extended his experiments, or had confidered them relatively to the work of goldfmiths, jewellers, &c. who are obliged frequently to pass through the fire those pieces which they have to work upon and fashion in various manners, I do not doubt, I say, that Mr. Alchorne would then have informed such artists, of the accidents to which gold alloyed with tin is liable, during the operation of annealing. He found that this mixture possessed a fort of ductility, and did not suppose it could be taken away by means of fire, which, on the contrary, in general, restores to metals their natural ductility, and renders them easy to work.

The opinion which has hitherto prevailed, refpecting the danger which attends the mixture of a fmall quantity of tin, either with fine or alloyed gold, appears therefore to be very well founded. It would indeed have been very extraordinary, that fuch an opinion should have been established without any foundation, when so great a number of artists have it in their power to afcertain the truth of fuch a circumstance; who cannot help immediately perceiving the harfhness of the gold upon which they work, and have every reason to induce them to fearch into the cause thereof.

This inftance, respecting an idea generally adopted, and supported by constant facts, and which most artists have taken for granted, without much enquiry into the matter, proves that we ought not to attack an established opinion without great caution; particularly when that opinion, like the one here treated of, is not in itself hurtful, and leads only to an excess of caution in working the most precious of metals.

Mr. Alchorne's experiments have long been recorded in the Philosophical Transactions, and have thereby acquired a degree of authenticity which demands respect. My only view in repeating them, and in giving an account of a material fact connected with them, but not mentioned by that skilful affayer, was to be useful to artifts.

artifts, and to give certainty to their operations. I trust I have effected this, by leaving them in possession of all those fears they have hitherto entertained, respecting the mixture of tin with any kind of gold.

Supposing even that my experiments are not so conclusive as they appear to be at first, still no inconvenience can result from them, except some useless trouble to those artists who, relying upon my observations, think it right to follow them. However superfluous they may seem, artists will do right to pay attention to them, rather than to work upon such gold as, from its harshness, they have reason to suppose alloyed with tin, and consequently incapable to bear annealing.

If it were allowable to form any conjectures, refpecting the cause of the fracture which takes place in plates of gold alloyed with tin, when they are annealed, it might be prefumed, (as tin quickly enters into fusion, while gold requires a very strong heat for that purpose, and a pretty strong one to be thoroughly annealed,) that the parts of the tin, being mixed with those of the gold in a fort of proportional equality, tend to separate from it by a speedy susion, and at a very low degree of heat; that they remain without consistence among these parts of the gold, while these latter preserve all their solidity, which they

do not lose even during the process of annealing. It seems, therefore, that the parts of that precious metal, when brought to a red heat between the charcoal, having no longer the solid connection formed by the tin, and having on the contrary a great number of small cavities, occupied by particles of that metal in a state of sustin, must necessarily have a tendency to distunite; whereas, the same accident does not happen in the pieces which have resisted annealing, and are slattened after being cooled; because the particles of tin have acquired consistence in cooling, and have thereby recovered their former state of union with the gold.

The accident here treated of does not take place in annealing a plate of gold alloyed with copper, for a reason opposite to that I have just pointed out, namely, because these two metals require nearly the same degree of heat for their sustain. Consequently, as the effect of the annealing heat is the same upon the one as upon the other, these metals, during that operation, preserve their usual consistence: indeed, they even preserve it when the annealing heat is carried almost to the point of sustain.

In fupport of the opinion I have just given, refpecting the cause of the breaking of the gold plates, I may observe, that when their surfaces are examined by a microscope, a great number of particles particles of tin, which appear to be disengaged from the pores of the gold, may be seen; and that, if these plates are annealed lying upon a flat piece of iron, or of silver, they adhere to such piece so strongly, by means of those particles of tin, that they cannot be separated without difficulty; and, in separating, they even bring off some small portions of the metal on which they were laid to be annealed.

I shall conclude these details, into which I have been led by the subject of my experiment, with observing, that the plates of gold here treated of may be kept from breaking, by annealing them on a smooth plate of metal, on which they are to remain till cold; whereas, when placed between burning charcoal, they are subject to twist and break, especially if they are laid hold of with tongs, in order to take them from between the charcoal, while red-hot.

XLIV. Lift of Patents for Inventions, &c.

(Continued from Page 288.)

JOHN DICKSON, of Dockhead, in the county of Surrey, Engineer; for a method of conftructing fleam engines, pumps, and other hydraulic machines. Dated July 14, 1798.

WILLIAM Row, of Newcastle-upon-Tyne, Merchant; for a mineral lamp-black. Dated

July 14, 1798.

RICHARD MARLOW, of the parish of St. Margaret, Westminster, Carpenter; for a method of hanging a window-sash, and window-shutter, without the appearance of lines and pullies, which are wholly concealed from the fight. Dated July 14, 1798.

WILLIAM DUPE, of Hammersmith, in the county of Middlesex, Gun-maker; for a method of manusacturing bars of a mixture of iron and steel, proper for double-barrel gun-barrels. Dated

July 23, 1798.

WILLIAM DOCKER, of Birmingham, in the county of Warwick, Slate Merchant; for a method of making pipes or tubes of a folid block of stone. Dated August 3, 1798.

STEPHEN

STEPHEN HALLADY, of the parish of St. Martin's in the Fields, in the county of Middlefex; for a new invention for the draught or moving of carriages of all descriptions. Dated August 3, 1798.

PHILIP CHELL, Engineer, and HENRY NI-CHOLS, Builder, both of Birmingham, in the county of Warwick; for a machine for lifting, raifing, and conveying boats, veffels, or other things, from an upper to a lower level, or from a lower to an upper level, on canals or rivers, to fave water, and prevent tunnelling. Dated August 3, 1798.

JOHN ASHLEY, of Islington, in the county of Middlesex, Plumber; for a new method of raising water from wells, of any depth, upon a very fimple and permanent conftruction. Dated Auguft 7, 1798.

THOMAS STATON, of Caftle - freet, Park, Southwark, in the county of Surrey, Machinemaker; for an apparatus for raifing beer, ale, wine, fpirits, oils, or any other liquids, from cellars, or other low places, to a higher or more elevated fituation. Dated August 7, 1798 ..

JOHN COCKRAN, of Paisley, in Scotland, Yarn-Merchant; for a method of spinning flax, hemp, and tow, by means of machinery wrought by water, and which may be wrought by fteamengines, horses, or any other power. Dated August 7, 1798.

XLV. Specification of the Patent granted to Mr. Joseph Bramah, of Piccadilly, in the County of Middlefex, Engineer; for his Invention of certain new Methods of retaining, clarifying, preferving, and drawing off, all kinds of Liquors commonly used for the Beverage of Mankind, more especially those Liquors called Malt Liquors, such as, Porter, Ale, Beer, &c. together with sundry improved Casks, and Implements, necessary to give Bis Contrivance the full Effect.

WITH THREE PLATES.

Dated October 31, 1797.

TO all to whom these presents shall come, &c.

Now know YE, that in compliance with the said proviso, I the said Joseph Bramah do hereby Vol. IX.

A a a declare,

362 Patent for retaining, clarifying, preserving,

declare, that my faid invention is described as follows; that is to fay, I do not rest the merits or value of this invention on the precise manner of performing the necessary parts thereof, or, in other words, on the specific methods herein adopted, for producing the objects of it; for, as invention confifts in those efforts of the mind which discover new objects, and also the best means of accomplishing them, I hereby declare, that I appropriate both, as the basis of my claim, and that to the full extent of their usefulness, in any and every new application of them I may hereafter discover, during the term expressed in my patent. This appears to me reasonable, and the unalienable right of every inventor; for, though the fubstance of invention is the birth of new objects, improved methods of obtaining those already known is still invention. Thus, objects and the means by which they are affected being distinct parts in every invention, they must certainly, according to the law of patents, be both of them the property of an inventor; and, as it fometimes happens that the objects of inventors prove abortive, while the means contrived to afcertain them are highly valuable, it is therefore I claim them both, as far as both are new. I shall accordingly hereunder, first, declare in words, what the true object or objects of this invention are: then shew, by drawings and refer-

ences, how the same is to be performed, in the best manner I am, in this unexperienced stage of a great undertaking, in judgement able to fuggest; and, in the performance of the work, (should it fall to my lot,) I here affure the public, who require this instrument as their guarantee, that they shall have the advantage of every future improvement I can make, in the means of giving this my invention its full effect. Now the objects of this, my faid invention, are briefly as follow.

First. I propose to preserve, and keep from flatness and acidity, all kinds of liquids used for the beverage of men, during fuch time as the faid liquors shall be on tap, or drawing off out of casks, let the period for this operation be what it may, whether days, months, or years; and thus render unnecessary the custom of putting liquors in bottles.

Secondly. I propose rendering water, and all liquors, perfectly pellucid, and free from heterogeneous matter, by an urged filtration, without the help of ifinglass, or other chemical preparation, commonly called finings. The advantages and good effects of fuch a performance, I need not flate to those who are acquainted with the organization of the animal kingdom.

Thirdly. I propose, by a simple and mechanical process, to convey, and cause all kind of li-Aaa 2 quors. quors to flow spontaneously, through small tubes, from the cellar, into any part of a house, above or below stairs, at pleasure. By this means, the cellar-door may be always locked, and thus freed from the injurious circulation of either cold or heat, at all seasons of the year; and, by this means also, adulteration, embezzlement, private drunkenness, over-filling, and the various other wastes in liquors, to which all families are exposed, will be wholly avoided, and, in public-houses, &c. infinite labour saved. That these are folid advantages, needs no argument to prove; as the master of every samily, and publicans especially, can testify the great necessity there exists for reformation in these matters.

Fourthly. I propose securing and drawing off all liquors, when occasion may require, by means of cocks constructed on a new principle, and made to lock on my patent-plan, so as not to be opened by any but those who have permission. This will enable every master (if he chuses) to draw, or witness the drawing, mixing, &c. of every drop of liquor he consumes. This, to publicans, &c. will certainly be a great acquisition, as the injury done them by careless drawing and mixing, &c. is very considerable.

Now, I declare, the four above-mentioned propositions comprehend the principal objects of my invention; and I propose the following instruments,

struments, as part of the means of accomplishing them, and on which the merits of the whole jointly depend, viz.

First. A cask on a peculiar construction, with

an apparatus to ditto.

Secondly. A pump, with fundry appurtenances.

Thirdly. A filtering-machine.

Fourthly. A new-conftructed vent-peg.

Fifthly. Sundry tubes, and a method of ma-

king them.

Sixthly. Various cocks, to be used in this procefs, and other hydraulic works, and their principles of construction.

Lastly. The manner of fixing and organizing

the whole apparatus.

These several points are fully shewn, and made appear to every person of competent knowledge in these arts, by the drawings and references hereunto annexed. I now again declare and affirm, that this inftrument, whereby I guarantee the reversionary benefits of this my invention to the public, as a price for the privileges given or intended to be given me, in his Majesty's grant, does contain a true and unreferved development of the principal objects of this my faid invention, without either over-rating or keeping back any part that has at this moment occurred to my knowledge and understanding; and also contains a true

a true description of every instrument, matter, and thing, I propose to use and apply, in carrying the same into full effect, both as to individual and collective principle and conftruction. And these I declare to be all of the best kind, and modified for the purpose in the best manner I am, in this infant state of the undertaking, able to devife, although; doubtlefs, time and experience may substitute various secondary improvements with respect to form and connection, which I again pledge myself to add, as I go along, for public good. But, at the same time, I must insist, that what is contained in this specification does fully and fufficiently comprehend the true foundation, as well as the necessary fabric, of this invention, and will be a competent guide to every practitioner, to the most distant periods of time.

Having thus candidly and fairly disclosed and exemplified the whole fecret, both of my intentions and the manner of giving them maturity. I most humbly hope that all courts and juries before whom my case may come, will, in their wisdom, and through the love of justice, protect and guarantee me, in spite of let or quibble, during the term granted by his Majesty, in the lawful exercife of all the privileges and interest allowed or meant to be allowed me, by the faid grant, as a reward for fuch labours as merit this distinction. In witness whereof, &c.

The drawings hereunto annexed are much more profuse than is necessary to explain the nature and defign of this invention *; but, in order to fhew how it may be ufefully applied and extended, I think it proper to infert them, by way of elucidating the whole, and begin with the plans and fections collectively.

Within the frame 1 2 3 4' (fee Plate XVI.) is comprehended the disposition of the whole scheme, in an organized flate, extended to various kinds of liquors, and I truft it is fo clearly and diffinctly laid down, that a fhort explanation will be found fufficient; and, to be as concife as I can, I have put the fame letters of reference on the plan, fection, and elevation, of each particular part. A, A, therefore, represent the plan and the section of a cask, which I call the drawing-off cask, represented in a vault below the level of the cellar-floor. This cask may be of wood, or of other proper materials, and of any dimensions in diameter and altitude, agreeable to the magnitude of the work where adopted. It must be made perfectly fmooth and cylindrical on the infide,

^{*} In the original drawings, four store-casks, for different forts of liquors, are represented. We have omitted two, in our plates, in order to obtain more room; the nature of the invention being as well shewn by two casks as by a greater number.

by boring, or otherwise, fimilar to the cylinder of a steam-engine; and must have a bottom in it, as at B, of fufficient strength to sustain the preffure of a column of liquor, of the same base dimensions, equal to the highest altitude to which the faid liquor is meant at any time to be therefrom conveyed. Into the upper end of this cylinder must be fitted the sliding-head or piston C; which head or pifton must be as strong at least as the bottom B, and must be made water-tight, all round its circumference, with leather, or other foft materials, fimilar to the pifton of a pump or engine for raifing water, &c. To the top of this piston is joined the stem or piston rod D, of a length at least equal to the height of the cask or cylinder A, and frout enough to perform the office hereunder described. On the top of this ftem D, is placed a wood box, guided and kept upright by the fliding-frame FF; which frame must be at least as high as will allow the piston C to move the full length of the cylinder A. This box must be of dimensions sufficient to hold as much fand, or other heavy and cheap materials, as will confiderably overbalance the column of liquor, as described resting on the bottom B. One of these casks, and its apparatus, must be provided for every kind of liquor meant to be thus preserved and drawn off, and may be placed as shewn in the plan and section A and 5, supposed

posed for malt-liquor, and in the plan 6 and 7, for wines. GG, is a main pipe, paffing along below the bottom, and in front of the casks A and 5 for malt-liquor, and 6 and 7 for wines, with lateral branches from it, communicating with each cock. In each of these branches, or in their junction with the main, is placed a cock, for the purpose of opening and shutting, at pleafure, the communication between the faid main and each cask, individually, as occasion may require, or, in other words, in order that each calk may be either filled or emptied, through the fame pipe or main GG, &c. At the extreme end of this main is a cock I, principally intended for cleanfing only. The other end of the main GG, as well as the main HH, is joined to the stop-cock K, which will be defcribed in its proper place. This cock has four branches, as shewn in the plan: the first of which communicates with the malt-liquor casks; the second with the wine casks; the third with the cleanfing-cock L; and the fourth, which is the feeding-branch, communicates with the filtering-machine M; which filtering-machine will also be separately described hereunder. Now, by turning the handle of the cock K, the liquors paffing through it may be directed, either to the wine, or malt-liquor cafks, or to the cleanfing-cock L, and, by this means, Vol. IX Bbb

any one of the faid casks can be filled at pleasure. N.N. are the plan and elevation of a pump, made on the common lifting-principle; the fuctionpipe of which communicates with the stop-cock O, which has also four branches, similar to the cock K, but is placed the reverse way; and the feeding-branch in K, becomes the dischargingbranch in O, which branch joins to, and becomes the fuction of, the pump N. Two of the other three branches, namely, PP, communicate with the general mains, which lead to the ftorecasks 8, 9, for malt-liquor, and 10, 11, for wines, placed in the cellar above, as in the fection. The mains have lateral branches, and stop-cocks, to each ftore-cask, exactly the same as those defcribed to the drawing-off casks, and will occafionally serve for both the purposes of filling and emptying them, in a way hereafter described. The fourth branch of this cock O communicates with a pipe leading to the cock p, which is either for the purpose of starting or filling the storecasks, or for cleanfing the whole with water, when necessary. There is one branch leads from the cock to the copper R, and another to the well or veffel S, for holding water; and, by turning the handle of this faid cock p, the pump will draw from either the copper or the well, and carry the liquor so pumped, either into

the store or drawing-off casks, as will be seen below.

From the upper end of the cylinder of the pump N, proceed two branches or forcingmains, one of which communicates with the filtering-machine M, and the other with the main leading to the store-casks; between this main and the pump is fixed a ftop-cock Q, which will open and flut that communication at difcretion. Now, suppose the whole of the apparatus, and all the utenfils, to be thus arranged, and the store-casks of every kind to have been filled in the common way, and ready for drawing off, we will, for example, begin with stale porter. Then, let the handle of the cock O, and that of the cock K, be turned to malt-liquor, and the cocks in both the mains GG and P, communicating with the casks, be opened; then, by working the pump, the liquor in the store-cask 8 will be forced through the filtering-machine M, into the main GG; and the cock at the bottom of the cask, section A, being open, the liquor will be forced into it by every stroke of the pump; and, supposing the pifton C, by the incumbent weight of the box E, to be descended to its lowest station, as in cask 5, then, by injecting the liquor under the piston, it will be raifed up, (on the principle of my new method of accumulating force,) as fast as the cask is Bbb 2 filled

filled by the pump, until the pifton and loaded box arrive at their highest station, as in the sectioncask A; and thus the piston and the weight above will be kept up, and rest on the liquor, until it is drawn off, when they will defeend, as the calk empties. Now, suppose the tube 12 to be inserted into the bottom of the cask A, and carried up to a proper place, appointed for drawing off, as flewn by tube 13, in cask 5; the cock 14 being then opened, the weight of the loaded-box E will, by its balancing the given column of liquor, as above mentioned, press down the pifton C, and cause the liquor to run out at the cock 14, with a force equal to the furplus of the balance, as aforefaid; and thus, all the liquor of the cask A will be discharged through the cock 14, with an uniform force, only minus the altitude of the cask; and not a fingle particle of atmospheric air can possible come in contact with the liquor, let the time of this operation be ever fo long; and thus the acidity, flatness, and unavoidable waste, heretofore common, will be prevented, and the cellar-door may be all the while kept locked. This example, I truft, is quite sufficient for all the -rest of the liquors, as the same process exactly will attend them. When the liquors in the store-casks are clear, the filterer may be taken out of the box, as will be shewn in

the description of that article, as it would, in that inftance, add a trifling unnecessary labour to the pump.

15 shews a scale, joined to, the top of the loaded box, which may be fo graduated as to shew, by the index 16, the quantity drawn out in any given time, even to a pint, or less, if required; and, by this means, the exciseman can take stock with accuracy, in an instant, without any instrument whatever but his pen; and, by locking up the handle of the pump, and cafing and locking up the index also, the liquors usually taken in casks will be kept as safe from fraud as those taken in the ffill; and it appears that, by thus fimplifying the duty of the excise-officers, fewer would be wanted; and, by preventing those mistakes which must frequently happen from intricate measurements, the general adoption of such a plan would ultimately prove a confiderable faving to the revenue.

By means of these cylindrical casks and loaded, piftons, I mean to convey water, as well as other liquors, in all directions, to the tops of houses, and elsewhere, for every purpose required, without having cifterns elevated in the ufual way. I also intend to apply my method of an urged or forced filtration, in all cases, for the purpose of procuring clear water, for the fupply of towns,

.374 Patent for retaining, larifying, preserving,

&c. as well as for private use, and particularly for the use of ships.

Fig. 2. (Plate XVII.) represents a section of the filtering machine, which may be made of copper, tinned on the infide, or any other materials proper for the purposé. Between the pipes A and B, which form the inlet and the outlet, and through which the liquor passes, is fixed a filtering-floor CC. This filtering-floor may be composed of various kinds of materials proper for the purpose, such as, porous stone, wood, leather, paper, slannel, sponge, fand in bags, or any fuch other materials as time and experience may prove best adapted to perform the most perfect filtration. When this filtering-floor is fastened down in its place, and the top of the box D fcrewed down, the machine is ready for use: and, when the liquor is forced in at the pipe A, by the pump, as in the general plan, it will be drove through the filtering-floor, and out at the pipe B, which leads to the drawing-off cask. When the lower part of the box has collected a quantity of dregs, or thick matter, it must be drawn out at the cock E.

Fig. 3 is the fection of a vent-peg, or, more properly, a stopper, for the vent necessary in all casks, when the liquor is drawn off in the common way. This little machine is constcucted exactly on the principle of an ejex or stench-trap;

and has the property of admitting air into, or excluding it from, the cask, without the attention of the person who draws the liquor, and cannot be left in a state not to do its office. A A, is a piece of brafs, with a taper screw at the lower end, to screw into the spile-hole of the cask; the upper end is of larger dimensions, and turned out in a cup or cylindrical form, with a flud or pin rifing up in the middle, as at B; through the centre of this stud is perforated a small hole. down through the shank or lower end of the peg. fo as to communicate with the interior part of the cask at b. The cavity which furrounds the stud being filled with water, the cap or thimble C must be inverted and dropped into the rabbet, into which its upper furface is fitted, and in which cap must be drilled fome small holes in the flanch, as at 1, 2, in order to admit the air freely; and, by its lower end or mouth being immerfed below the end of the ftud, nearly to the bottom of the cup, the air will be prevented having ingress or egress, except when the pressure of the air is augmented by drawing out the liquor; at which time, the air will force its way into the cask, through the water contained in the cup, as shewn in the drawing.

Fig. 4 is a machine, shewing a new method of making tubes of lead, or other foft metals, fuch

as tin, pewter, &c. of all dimensions, and of any given length whatever, without joints. This is performed by a process of pumping or forcing lead, &c. in its liquid state, through metal moulds; by which, tubes, of any given shape or fize, may be made with great expedition, and perfect accuracy. AA, is an iron melting pot, in the centre of which is fixed the pump B, which is made of iron or brass, with a piston so nicely fitted into it, as to be capable of preventing liquid lead from paffing it, when preffed down with confiderable force: in the bottom of the pump is fixed a fuction-valve C, made of metal, and ground lead-tight. On the opposite side of the pump is an arm or pipe, conveyed through the fide of the melting-pot A A, where the junction is also made tight. On the outfide, over the mouth of the aperture of this pipe, is fixed the projecting. tube or mould D; the infide of which is bored perfectly fmooth and cylindrical, and its interior diameter is equal to the outfide dimension of the tube intended to be made. The end of the mould or tube D, next the pot, and where it is joined thereto, is made confiderably wider than the mould itself, and this part gradually verges to the fide of the mould. In this wide part, close to the fide of the pot, is fixed a cross or bridge, into the centre of which is fixed a mandril, or cylindrical

drical bar of iron, or fteel, turned perfectly smooth and true, and of a diameter exactly equal to the infide or bore of the pipe to be made in the mould D; and it must be in a small and regular degree diminished in its diameter towards the external end, which end must terminate with the end of the mould, or the eabouts. This mandril, fhewn at E, must be so fixed into the cross or bridge, as to be perfectly in the centre of the mould, at the front, as well as at the back end; and there must be sufficient openings in the cross or bridge, in the wide part of the mould, to allow the lead to communicate, in its liquid state, to the front of the conical part, fo that it may again unite in a fluid state, after passing the cross or bridge which feparates it, and into which the mandril or infide core is fastened. The mould D must likewise cross the fire-flue of the meltingpot, fo as to be kept always hot, that the lead which then furrounds the mandril or core may be kept in its fluid state, nearly to the external point of the mould. This done, and the pot A A filled with liquid lead, then, by working the pump with a lever of fufficient power, the lead will be pumped or forced through the mould; and its heat therein being fo regulated as to chill a little, before it approaches the open air at the point of the mould, it will keep iffuing out in a Ccc folid Vot. IX.

folid state; and thus, pipes, of any length and fize, may be made perfectly found, and without a single joint. In order to avoid the nicety of causing the lead to chill of its own accord, while passing through the mould, it will perhaps be proper to insert the soint, or extreme end of the mould, into the side of a cistern of bot water, or the like.

The next and last article to be described is my improved cocks, to be used in this work, and for every other purpose where cocks are applied. The peculiar merit of my method of constructing and making them is as follows: that is to fay, I have fo contrived them, that when the cock is thut, the liquor, meant to be retained thereby, shall rest or gravitate, with its whole force, on the upper or larger diameter of the conical key. or stopper which opens and shuts the water-way, in fuch a manner that the faid gravitating force shall always press the said conical stopper or key down to its bearing or feat, into which it is fitted by grinding, or otherwife; contrary to all cocks made on the old principle, where the gravitatingforce of the fluid, always refting against the oblique fide of the cone, endeavours confrantly to lift it from its feat, and causes it to leak. By this means, the cone or key of this cock requires no rivet, or any other contrivance to keep it in

its feat, but (directly contrary to the old principle) the more it is pressed upon by the incumbent sluid, the better it fits, and the closer it shuts; and, instead of its getting impersect by use, it will gain persection; and, from having no rivet, &c. will always move free, and cannot set fast, contrary to those on the common principle, which will, from the necessity of their being kept down by a rivet, or otherwise, always work stiff, or leak.

One example will be fufficient to fhew plainly how this is to be performed. Figs. 5 and 6 are the plan and fection of a stop-cock. The conical stopper A, of this, as well as that of every other kind of cock, is made hollow on the infide; and the cavity may be of a fimilar shape with the outfide, for the fake of faving metal, or it may be otherwise. The top of this interior cavity, or larger end of the cone, may be cut quite open, and left like a cup; or it may be left whole, like a lid, and a hole only perforated through it, fufficient to let the liquor pass and fill a small fpace left between the cone and the cup B; by which means, the liquor will prefs against the cup, and re-act on the head of the cone, and force it down. At the lower or less end of the cone is the axis or fpindle C, which passes through the bottom of the external case or socket of the

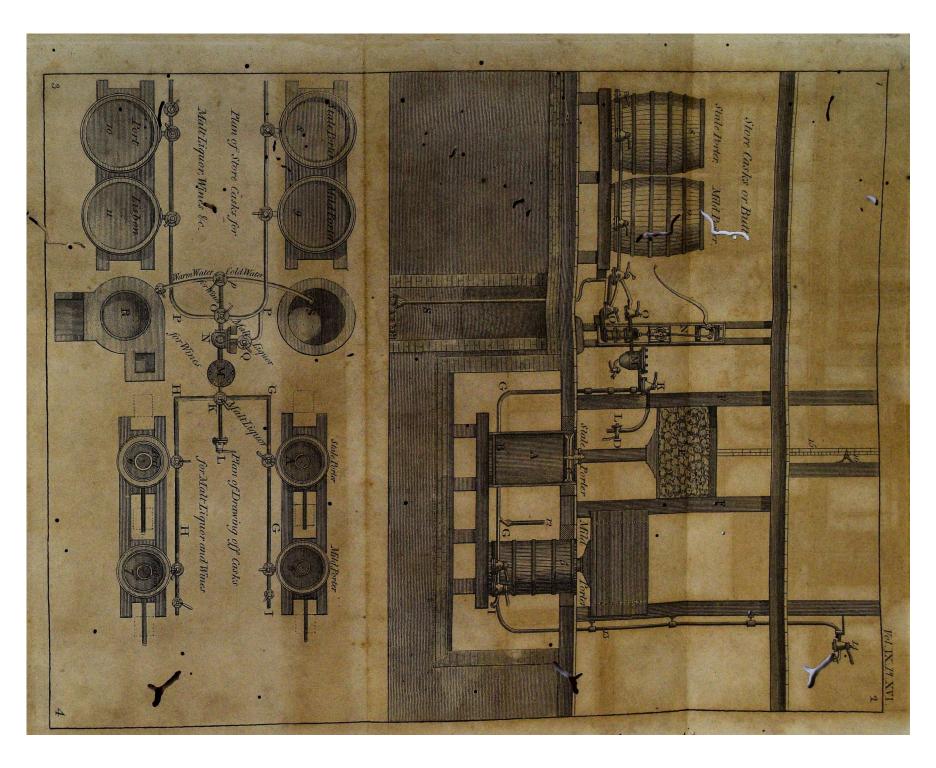

Ccc 2

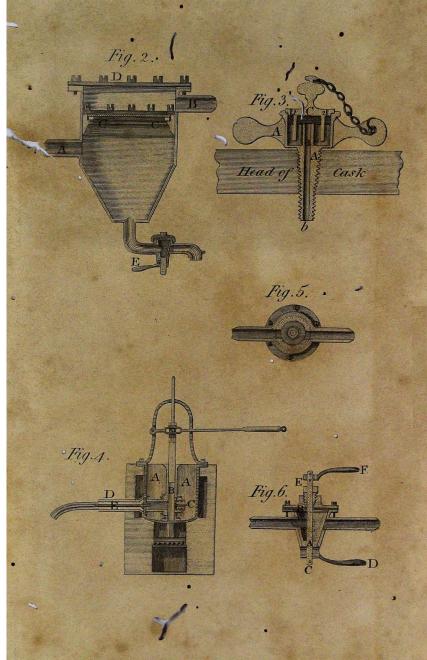

cock.

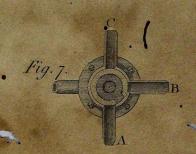

cock. To this axis or spindle is fixed the handle D, by which the cock is opened and fhut; or, in some cases, it may be opened by the spindle E, passing through a stuffing-box to the handle F. One of the ribs between the water-ways of the cone must be cut away, so as to leave one rib only, fo that, when the cock is flut, the viquor on the driving fide may rest on the cone, to keep ir down.

Figs. 7 and 8, (Plate XVIII.) represent a cock with fundry water-ways, where the liquor enters in at the head of the cone; and, by having one aperture only in the fide of the cone, it may be turned fo as to discharge the liquor at A. B. C. &c.

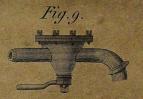

Figs. 9, 10, and 11, are examples of different forts of cocks, and the means of applying them in different brewhouses.

XLVI. Specification of the Patent granted to ABRAHAM BOSQUET, of Stangate, in the Parifosof Lambeth, in the County of Surrey, Equire, formerly of Sandymount, in the County of Dublin, and late one of his Majesty's Commissaries of the Musters; for a Method, by the Application of which, his Majesty's Navy, and all trading Veffels, may derive Durability, Soundness, Staunchness, and many other Advantages.

Dated June 8, 1798.

TO all to whom these presents shall come, &c. Now know ye, that in compliance with the said proviso, I the said Abraham Bosquet do hereby declare, that the nature of my said invention, and the manner in which the same is to be performed, is particularly described and ascertained in the schedule or particular hereunder written. In witness whereof, &c.

The Schedule above referred to.

A measure for effectually avoiding the intolerable nuisance and destructive effects of rats on board board ships, and for the prevention of leakage, or making bilge water, and also for the better preservation of his Majesty's ships, and all trading vessels, from decay.

The above evils and inconveniencies have long existed, and are attended with the most destructive confequences to ships, their provisione, and merchandizes, and the health of feamen; the following fimple and falutary measure is not attended with any comparatively material expence, and will, I trust, appear at first view to be adequate, in the fullest extent, to the defired end. The rapid decay of ships, and their perpetual repairs, are attended with an enormous expence, both to the nation and individuals, and claim the most ferious attention, particularly as the oak of this country, which is the best of all other, cannot much longer fupply the increasing occasion for it. The waste in provisions, and other deftructive effects occasioned by rats on board thips, are of inconceivable magnitude, and for these no remedy has heretofore occurred. The perpetual danger and labour attendant upon leakage in ships, cannot be prevented by caulking, or any other precaution hitherto used, though frequently the loss of the ship is the consequence, and much injury to the cargo always enfues; nor is the foul, damp, and fragnated air in thips, unworthy every confideration which can afford redrefs.

drefs. To apply at once a fovereign remedy to all these evils, unattended with a fingle inconvenience, the mode I have adopted is, the occupying or filling up the void spaces between the planks, lining, and timbers of the ship, to which the planks are bound, with hot or melted pitch, tempered, as far as found necessary, with a due, yet fmall, proportion of tar, common glue, beeswax, and tragacanth, to render the pitch less brittle, more tenacious and durable. These being blended together in the kettle, there is to be mixed therewith a certain portion of cork-shavings, and small bits of waste cork-wood; but, in case enough of these cannot be procured, cut straw, bullrushes, flocks, old junk, and the like, may be fubstituted. But, in those parts where the timbers are remote from each other, pieces of cork-wood, or flips of deal, may be introduced; which will render lefs pitch, &c. necessary in those spaces, and at the same time diminish its weight.

The manner of applying the composition is fimple and expeditious, and is as follows: The Thip being on the stocks, and ready for the laying and application of her floor and lining, the floor being first laid, and a few planks of the lining well jointed, laid on, and bound to, the timbers, to the height of about three feet all round, the composition is to be poured in, between the timbers, planks, and lining, as hot as possible: this, by its weight and fluidity, will introduce itself under the floor, from either fide to the keel; infinuating and faturating every space and crevice, however minute. Thus much being done, four or five feet more of the lining may be put up, all round, and the composition poured in . as before; and fo on, till all is complete to the necessary height. Ships already built may be faturated with very little additional trouble or expence: the ship being brought into a dry dock, and a little of her floor taken up, that she may dry thoroughly, the floor being again laid down, a plank of the lining, all round, at two or three feet above the level of the floor, is to be ripped off, and the composition poured in, as before mentioned. The planks being replaced, another plank, five or fix feet higher, all round, to be removed, and fo to proceed, till all is finished. This measure will effectually prevent rats from finding an habitation on board ships, as those spaces between the timbers are their ftrong holds, where they cannot be come at or annoyed, and where they carry their plunder, breed, die, and rot; the bad effects of which are too often ferfibly felt. To pitch and tragacanth, rats have an averfion, and never touch the one, or approach the other, in any manner, if they can avoid it. How far these spaces being so filled up, might stiffen the ship, I know not; but I think that the interior

terior parts, in which the nails, pins, bolts, and trunnels, are inferted, as well as those themselves, being much longer preserved from decay, must not only preserve their strength, and soundness, but retain their hold, and remain firm and un-'shaken in the timbers, to a much greater extent of time, and of course the ship maintain her stiffness, in consequence thereof; but, to a certainty, it will have the important effect of wholly preventing bilge water, and small leaks, which refult from fraining, want of caulking, &c. &c. and perhaps render caulking altogether unneceffary. This composition will have the effect of fo much ballast, in the best position in which ballast could be placed, as it will nearly occupy the centre of motion; and, in case of the ship filling by any accident, would operate as a buoyant body in the fhip, and occupy the receptacle of feveral tons of water, which would otherwise find place between the timbers. This measure will most effentially conduce to keep ships sweet and dry, and effectually preferve the planks, timbers, &c. from that rapid decay to which they are at present subject by the injurious effects of the water, which is at all times disposed to infinuate itself; rotting the pins, iron bolts, trunnels, &c. ouzing through the lining, to the injury of the cargo in contact therewith; leaving a damp and flimy matter behind, and rendering Ddd Vol. IX.

the air in those spaces, already foul, of the most noxious quality, and which no ventilation can, even for the moment, fufficiently purify. It will also, I believe, be obvious that foundering can rarely happen to fhips fo fortified; not only because their fides will be nearly as staunch as if there was not a joint or feam throughout; but, even in case of a bad leak, at any time, finding its way into the ship, it would be at once discovered, and it could not dripple down between the planks and lining, and of course would shew itfelf at the part admitting the water; but I am of opinion that ships, in general, would not make a quart of water where they at prefent make a ton. This composition being light, firm, elastic, and adhefive, and ftill rendered more light and tenacious by the admixture above mentioned, will comply with the planks, timbers, &c. in all difpositions to warp or strain, and thereby prevent the fhip making water at her feams, when fhe might otherwise fill.

XLVII. Specification of a Patent granted to Mr. CHARLES FEARNE, of the Inner Temple, London, and Mr. James Gray, of St. Margaret's, Westminster, Gentleman; for a Method of dying Paper, Card-paper, and White Leather on the Grain Side, of various Colours.

Dated January 25, 1770.—Term expired.

TO all to whom these presents shall come, &c. Now know YE, that in compliance with the faid proviso, we the faid Charles Fearne and James Gray do hereby declare, that our faid invention of a method of dying paper, card-paper, and white leather on the grain-fide, of various colours, different in quality, and superior in many respects; to any hitherto used for those purposes, is described in the manner following: that is to fay, the colours for leathers are thefe following; to wit, red, blue, green, black, with various fhades of each. The reds are various, and are produced by a tincture of carmine, by a tincture of cochineal and madder, or a tincture of Ddd 2 cochineal

cochineal heightened by a folution of tin; or, lastly, from decoction of brazil and alum, in malt liquor. Blue is produced from a folution of indigo in oil of vittiol. The green is an admixture of the blue with any yellow tincture, at pleafure. Blacks are produced from the blue added to a tincture of galls, fumach, and Campeachy-wood, stricken black by tincture of steel, or fal martis. The colours for papers are all the above-mentioned, prepared in the fame manner, together with yellow, purple, orange, brown, and their feveral intermediate degrees of variation. Yellow is produced by a tincture of French berries with faffron, as also by most of the yellow dies now commonly used for those purposes. Orange is produced by the admixture of the yellow with madder. Purples are produced by the admixture of logwood with the blue tincture; or from cochineal, with fal martis, or tincture of fteel. Browns are obtained from Arnotto and Japan earth, with galls and fal martis.

With respect to leathers, the method of application is, to dip them on the grain side, so long and so often as may be found requisite for the depth of colour desired. This is to be done in a flat pan or vessel, capable of receiving the leather extended therein, with its grain side on the liquor. When dry, they are to be washed with a

spunge,

fpunge, and foap and water, and finished by rubbing with dry flannel, except the blacks, which are to be oiled before they are washed.

With respect to papers; they are to be procured from the mills unfized; and, in that state, tenderly paffed through the colouring-liquor, mixed with fuch a portion of fize as the intended degree of stiffness may require; which may be done, either by the hand, or by a contrivance fimilar to that used in the paper-mills for fizing their paper; and this is to be continued till the paper shall have acquired the intended depth of colour. After which, it is to be hung up on fine horse-hair lines, or on glass tubes; and, when the colour shall have become what the dyers call fet, then it is to be paffed through cold water, and be hung up to dry; after which, it is to be preffed and polished, according to the use for which it may be intended. In the above applications, the tinctures are to be used hot or cold, as may best fuit the depth of colour required. In witness whereof, &c.

XLVIII. Specification of the Patent granted to Mr. William Finch, of Woombourne, in the County of Stafford, Iron-master; for certain new Methods of making Nails and Spikes, of Iron, Copper, and other Metals, by Means of certain Machinery put in Motion by the Force of Animals, Water, Wind, or Steam, instead of making them by Hand.

Dated July 28, 1790.

TO all to whom these presents shall come, &c. Now know ye, that my machinery for working the hammers, by which all manual labour will be faved, confifts of one main fhaft, caufed to turn round, in either a horizontal or perpendicular direction, by means of a water-wheel, or the effects of fire by a steam-engine. Such main or principal fhaft will put in motion, by means of cogg and round or tooth and pinion wheels, other counter shafts or barrels, whereon are fixed coggs, tappets, or arms; which coggs, tappets, or arms, striking upon the helves or shafts whereon the hammers are fixed, work the fame in either a lift or tilt manner. Also, to make three divisions of hands in the manufacturing of headed nails; namely, one man, woman, or child, to carry the heated rod to the man, woman, or child, ftationed before the hammer; which man, woman, or child, by mere activity, will, with one hand, not only form the largest fized nail, but a far greater

greater number in the fame given time; when the third man, woman, or child, will, with the fame kind of hammer, head and finish a number of the faid shanks together, leaving them truer made, and better for use, than the present mode. Alfo, by a division of hands, will make such nails as require no tool or frame to be headed in; namely, the one, as heretofore mentioned, to carry the iron from the fire; and the other, as stationed before the hammer, to finish them. Alfo, by heating many rods in one fire, there will be a faving of coal. Alfo, by the more speedy motion of machine-hammers, feveral nails will be made at once heating of the rod; whereas, by the old method, only one is made, confequently, there will be a great faving of yeild. Alfo, the motion being regular, independent of strength, a child will be able to make the largest nail or spike. And a farther and confiderable benefit will arise to the manufacturer by this mode; namely, that he will have his bufiness done at one place, or under one roof; whereas, by the old method, the workmen live many miles afunder, and cannot be overlooked. Likewife, by this method, the limbs of those employed in the manufactory will be preferved to the end of life; whereas, in the old method of working, men are frequently lamed in feven or ten years, and obliged to be maintained by the parish. In witness whereof, &c. XLIX.

XLIX. On the Cause of the Smut in Wheat. By Mr. JOSEPH WIMPEY, of North Bockhampton.

From the Letters and Papers of the Bath and West-of-England Society for the Encouragement of Agriculture, &c.

IN a former paper on this very difficult fubject *, I observed, that it was no unusual thing
to meet with ears both of smutty and sound corn
issuing from the same root. Also, that it frequently happened, that smutty and sound grains
were to be found in the same ear; and that I had
then by me the corn I had picked out of such
an ear. It contained forty smut balls; 21 grains
that appeared to be perfectly sound; and sive
grains which had one end black and smutty,
and the other sound. These I made the subject of experiment, the result of which was as
follows.

On the 2d of September, 1789, I put the twenty-one grains above mentioned into a two-

^{*} The paper here referred to is printed in our feventh volume, page 405.

ounce phial of pump water, which I very well shook together. It was then fet by till the next day, when the water was poured off, and the corn divided into two parcels. Having filled a two-quart garden-pot with common mould, ten of the grains were fet in five holes, about two inches deep. The other eleven grains were returned into the phial, it being first nearly filled with a ftrong pickle of falt and water. After standing 24 hours, these were also set in a garden-pot, in all respects similar to the other. My intention in these different processes was to difcover, 1st, if corn from a fmutty ear, merely by rincing in fimple water, would produce found corn, free of fmut; and, 2dly, if a ftrong folution of falt and water would more effectually answer that defirable purpose, as was generally believed, and infifted on.

The beginning of December, I observed the plants seemed much crouded, and wanted more sustenance than the small quantity of earth the poes contained could supply. On the 8th day, therefore, I took them out of the pots, and planted them in a row in the field, about eight inches apart, keeping, however, the plants of each pot separate. There was no perceivable difference in the plants; in both pots they had shot vigorously, and it was truly amazing to see the immense quantity of roots the pots contained;

VOL. IX.

Eee

the

the fides being completely lined, with the fame running round and round, to an incredible length; from whence it feems very probable, that the roots of wheat, in good land, well pulverized, may extend, and collect fustenance, at fome feet distance from the parent feed.

At this feafon, vegetation is nearly at a stand. It was the end of March, or beginning of April, before the plants began to shew the least appearance of recovery from the check occasioned by transplanting: however, they then began to shoot vigoroufly, and at length acquired an uncommon degree of strength, length, fize of ear, and plumpnels of grain, having from 12 to 24 offsets or ftalks from each plant. I reckon I am much within compass, in supposing that the produce of these 21 grains was not less than 15,000, and the grain as plump and fine as ever I faw, and every corn perfectly free from fmut. It would be ridiculous to suppose, that this corn was in any respect better than it would have been from found and perfect feed: its extraordinary vigour I impute folely to its being transplanted into fresh ground, well pulverized; which could not fail to give much additional sustenance and strength to the plants, and would probably afford the greatest produce possible, on any given quantity of land. But I am fenfible it could never answer the extra expence, nor be at all practicable, on a large

large scale, notwithstanding some mere speculative men have wildly imagined the contrary.

From this account, it is as certain as experiment can make it, that a smutty crop of wheat is pot the necessary result of sowing seed from corn that is fmutty; also that it does not owe its corruption to any vicious principle or defect in the feed. In this experiment, we fee the feed rinfed or foaked in fimple water, produced as clean and perfect grain as that which was foaked in a strong folution of falt and water; and therefore were not in the least tainted by the fmutty grains in the fame ear, nor at all affected by the cause, whatever it was, that vitiated them; or, if they were, that the foaking and rinfing in fimple water was as effectual to the preservation of the crop from fmut, as the strong pickle. But it is a truth univerfally known from experience, that in unfavourable years, corn is generally fmutty, notwithstanding brining, liming, and every precaution hitherto used to prevent it. From all which it clearly appears, that the general cause of the fmut does not exist in the feed, but is owing, if not altogether, yet in a very great degree, to some vitiating principle in the air, a constant concomitant of cold, wet, ftormy, tempestuous summers, which are ever attended by fmutty crops. My reason for supposing the smut may sometimes possibly be derived from the feed, will appear hereafter.

In the above experiment, one thing occurred which I must not omit, for it well deserves to be noticed. One part of the feed was foaked in clear water only, the other in a ftrong folution of falt and water. I could perceive no difference in the plants, on a comparative view, from the time oftheir first coming up to the maturity of their growth, except in their tillering. The plants in both experiments were equally vigorous, equally tall and ftrong, the ears equally long, large, and full, and the grains equally plump and heavy; but those steeped in the brine tillered out considerably more, that is, put out many more stalks, than those steeped in water only; consequently, were much more productive. What the superior fructification was owing to, is well worth enquiry. The feed was out of the fame ear; and, though fet in two different spots, it was in the same earth, and transplanted into the same ground; the culture in every respect the same; the only difference was, in one the feed was steeped in clear water 24 hours, and then planted; in the other, after being steeped 24 hours in the same water, it was freeped 24 hours more in falt and water. The question is then, and a very interefting one it is, whether the fuperior fecundity of the latter was owing to the feed being fleeped twice as long as the other, or to its being impregnated with the falt used in the folution, or to fome fecret cause not discovered, and possibly not capable of being discovered, by the experimentor.

By repeating and varying these experiments, it would be eafy to discover; whether fertility is promotable by fleeping a longer or a less time in vater; and, 2dly, if water in which a good quantity of falt has been diffolved, does not encourage and promote vegetation more than fimple water. If it should be found to do so in any confiderable degree, I cannot have a doubt but a ftrong lixivium, made of wood ashes, would promote it much more. I have always been of opinion, that fuch menstruums were useless, or at most, that their aids extended no farther than the first rudiments of plants; but the fact recited above firongly inclines me to repeat the experiment, in order, if possible, to fully ascertain the facts.

In the next place, I shall give an account of an experiment made with the five grains mentioned above, which were smutty at one end, and found at the other. These were set in a small garden-pot, like the former, one of which only came up. In the spring it seemed to want more room; I therefore dug a hole in the ground, and, taking the mould out whole from the pot, it was planted in the same, without disturbing the roots. It soon grew vigorously, but never had

the healthy and robust appearance of the others. It had always a fickly greenish yellow look, which betrayed its malady, notwithstanding its stems grew to a good height, and tillered surprisingly. I counted 24 ears from this single grain, most of them of a good length, but lank and then, very unlike the appearance of those smutty ears which are not affected till the blowing season; for these very often are the finest and plumpest ears in the field, till that time.

Of these 24 ears, 23 were entirely smutty, not a sound corn could be sound among them. The other was quite a small underling ear, which did not appear till a full month after the others, but always bore a healthy appearance. This ear produced 14 corns only, and those small and thin, but sound and perfect. These were planted again last August, and are now as sine and promising as any corn in the sield.

From this experiment it feems to appear, that a grain which is vitiated with the fmut, yet has enough of the vegetative principle found to enable it to grow, infallibly produces fmutty grain. That one ear, and one only, out of 24, should be found, is indeed very strange; but perhaps not more for than that, in the animal creation, the offspring of a distempered sire may in general be affected by the vitiated stamina of the sire, yet some one

or more escape the hereditary taint, and apper perfectly found.

From these, and the experiments of the former paper, the following corollaries are clearly deducible:

First. That found grains from very smutty ears, produce as clean and as found crops as feed from corn that is perfectly free from smut.

Secondly. That feed from the foundest and cleanest crops doth frequently, in wet, cold, unfavourable seasons, produce smutty crops, in spite of steeping, brining, liming, change of seed, and every device and invention which the wit of man hath ever practised.

Thirdly. That in fine, dry, warm fummers, it frequently happens there is little or no fmut at all; and that, in many inflances, where fmutty feed has been fown, the produce has been clean, and perfectly free from the fmut.

Fourthly. That the fmut is not an hereditary difease, proceeding from a corrupt or vitiated stamina in the seed; but usually and almost entirely occasioned by some blight or vitiating principle in the atmosphere, which corrupts or destroys the vivifying principle, at the time of its blowing and secundation.

Fifthly. If the fmut ever proceeds from diftempered feed, it can be only from such as hath the germ or feminal principle found and entire; for mere fmut balls are as incapable of vegetation as powder of post, or the most effete matter in nature; but this is a case so rare, as not to be adequate to the production of a millionth part of the smut that happens; therefore, it must generally proceed from some malignant principle, which at some seasons subsists in the air.

Sixthly, and laftly. If the cause of the smut does not subsist in some latent or occult corrupt principle in the seed, but is generally occasioned by the intemperance of the air, six or eight months after the seed is sown, it seems perfectly nugatory to use any means to remedy or prevent a disorder which has no existence, even in its cause, and most probably may never happen; unless it could be made appear, that those means bestowed such a degree of strength and vigour to the plants, as might render them less susceptible of any malignant impression from the atmosphere, which might happen to reign during any future stage of their growth.

I have now feveral more experiments in profecution, having fet many fmall quantities of found grain, picked from fmutty ears at different times. At prefent they all appear very promifing; but the refult cannot be known till the next harvest, when, if found interesting, I may probably request leave to lay it before the society.

L. Description of a quick and easy Method of conerting Weeds, and other vegetable Matter, into Manure. By Mr. H. BROWNE, Chemist, of Derby.

From the Transactions of the Society for the Encouragement of Arts, Manufactures, and Commerce.

According to a promise I made some years since, I beg leave to communicate to the Society for the Encouragement of Arts, &c. and (if thought worth notice) by them to the world, a composition for manure. Fearful it would not answer the purpose so fully as I could wish, I deferred it from year to year; but I now find, by numerous trials, made by my friends as well as by myself, the very great utility of the composition, as well as its cheapness, with the capability of its being snade in any situation, and in any quantity. The mode of making it is as simple, as I trust it will be found productive. It is nothing more than Vol. IX.

green vegetable matter, decomposed by quick or fresh-burnt lime. Upon a layer of vegetable matter, about a foot thick, a very thin layer of lime, beat small, is to be laid; and so on, vegetable matter, then lime, alternately. After they have been put together a few hours, the decomposition. will begin to take place; and, unless prevented, either by a few fods, or a fork-full of the vegetables at hand, the mixture will break out into a blaze, which must at all events be prevented. In about twenty-four hours, the process will be complete, and you will have a quantity of ashes ready to lay on your land, at any time you wish. Any and all forts of vegetables, and weeds of every description, if used green, will answer the purpose. They will doubly serve the farmer, as they will not only be got at a fmall expence, but will in time render his farm more valuable, by its being deprived of all noisome weeds.

But, if this composition answers the purpose, as I flatter myself it will, a very short time will lee almost every weed destroyed. Supposing that to be the case, I have made a calculation with clover, grown for the purpose; for instance, I will take one acre of clover, which at one cutting will produce from sourceen to eighteen tons of green vegetable matter, and will require about three tons of lime; this, when decomposed by

the above process, will yield ashes sufficient to manure four acres, the value of which I estimate at something under four pounds. The clover, according to the value of land here, at two pounds, which, taking the average of the kingdom, is too much: the lime also at two pounds; but that will vary, according to the distance from which it is to be setched: take them together, I think the above will be about the average value. Now, if this is the case, and, as far as I have been able to try it, I find it so, how valuable must this method be to the community in general! If it answers the purpose, I shall feel myself much obliged by the Society making it as public as they possibly can.

The vegetables should be used as soon after they are cut as possible, and the lime as fresh from the kiln as the distance will allow of; as on those two circumstances depends the goodness of

the composition.

LI. Farther Observations on the Process for converting Cast into Malleable Iron. By Thomas.

Beddoes, M.D. *

From the Philosophical Transactions of the Royal Society of London.

SINCE I described the process known among the workmen by the term puddling of iron, I have several times reconsidered the explanation I there attempted, of the phænomena it presents. My explanation could not indeed but be in great measure conjectural; and subsequent reflection excited in my mind a very lively wish to ascertain, in a decisive manner, the nature of the process. The following experiments will, I flatter myself, serve to determine the degree of considence with which the principal points of my theory may be received, though they will not afford a solution of all the questions which my former observations might suggest to an acute philosopher.

^{*} Dr. Beddoes's first paper on this subject is inserted in our eighth volume, page 282.

They were undertaken in order to ascertain, first, whether any elastic sluids are really extricated during the conversion of cast into malleable iron; secondly, what is their nature; and, thirdly, whether they vary at different periods of the process, as I concluded, from the appearances in the surnace. It seemed of less consequence to ascertain their quantity: I did not, however, neglect this object of inquiry, but some very curious circumstances prevented me from attaining it.

Experiment I. Six pounds of dark grey melting cast-iron were put into an earthen retort: a glass tube was luted to the neck, and its extremity was immerfed in water; the retort was placed in a wind-furnace. Before the retort and its contents could be supposed to be red-hot, inflammable air came over. It burned with a deep blue flame, and was in no degree explofive. It rendered lime-water turbid, and was partly absorbed. When the retort had been heated about an hour and a half, the air, which was coming over pretty copiously, (that is, at the rate of an ounce-measure every nree minutes, upon an average,) fuddenly ceafed, and the apparatus, on examination, proved to be no longer air-tight. The retort was found to be cracked; the lumps of iron had none of them been

conglutinated together.

Experiment II. Four ounces, Trov, of the fame iron were put into one of Mr. Wedgwood's earthen tubes, glazed, and closed at one end. That end of the tube was inclosed in a barrelshaped crucible; the interstice filled with fand, and the crucible reclined, fo as to form a very fmall angle with the horizon: in other respects, the apparatus was disposed as before. On the application of heat, air was again extricated, fooner than I should have expected, of the same inexplofive inflammable kind. About one-feventh of that which came over first, and which traversed the water of the receiving-veffels, was absorbed by milk of lime. The refidue burned flowly, with a flame apparently not fo deep as before the carbonic acid was separated.

In this and the former experiment, the elastic fluids were most rapidly extricated on the first impression of a red or white heat; afterwards they came over much more slowly: during a considerable part of this experiment, you might count twelve, slowly, between every air bubble.

When the utmost power of the furnace has been exerted for three hours, a phænomenon occurred which produced some surprise in every person present; and there were several who had

been

been abundantly accustomed both to chemical and metallurgical operations. A confiderable abforption took place, and, for about half an hour, it was necessary to blow air up the glass-tube, to prevent the rater from rifing into contact with the iron. It afterwards appeared, that the lead of the glazing was revived, which sufficiently explains the absorption.

586 grains only of the iron had been completely fused. The furface of two of the unmelted lumps was curiously covered with numerous small blifters of metallic lead.

About feven hours after the fire was first kindled, it was discovered that the apparatus had failed. I had examined the air that came over, immediately before this accident, both by means of lime-water and milk of lime, without discovering any vestige of carbonic air.

The iron weighed altogether three grains more than at first. But the adhering lead, and a quantity of lead also which was incorporated with the iron, concealed a real and probably a considerable loss of weight. The phænomena it exhibited, when put into weak vitriolic acid, and the vitriol ded lead which was formed, indicated the presence of this metal in all the superficial parts of the mass. When it had been kept some time in vinegar, it dissolved readily enough in vitriolic acid,

acid, at first, but the folution soon ceased, or became very flow.

Experiment III. A coated flint-glass retort was employed in this instance. The apparatus resisted a strong heat for two hours; and air, of the heavy

inflammable kind, came constantly over.

Experiment IV. A coated fetort of crown-glass, containing fix ounces, Troy, of the fame iron, was placed on a crucible nearly full of fand, and difposed as in the former experiments. I now wished to measure the quantity of the air, and I therefore determined to receive it in mercury: it would have been in vain to attempt this in water, on account of the carbonic acid air. About twelve o'clock, the retort was judged to be of a dull red heat, and inflammable air came over. The orifice of the transmitting glass tube was now covered to the depth of half an inch with mercury, when the discharge of air instantly ceased; the lute seemed entire. Some of the mercury being removed, fo as to leave just enough to cover the mouth of the tube, the air immediately iffued again in bubbles; a proof that the apparatus was entire. The mercury was again poured into the trough, and in an instant there was a ceffation of air. The mount of the tube being uncovered, and a lighted paper applied, a blue flame appeared, and continued to burn, fo great was the quantity of air discharged:

discharged: the orifice of the tube was onetenth of an inch in diameter. We found that this constant flame could be produced at any time, during three hours and a half. When water was substituted in place of mercury, air issued flowly, and as if with difficulty, under a pressure of five inches. When only half an inch was left over the mouth of the tube, fmall bubbles afcended freely: during a confiderable time, I counted four, flowly, between each of thefe bubbles. I did not collect above three ounce-measures of air, and this contained carbonic acid. It was past four o'clock when the apparatus ceased to be airtight, and the fire had been kept as strong as possible. The iron was most completely fused. There was a good deal of revived lead within the retort; there were also many globules in the neck. Probably fome broken flint-glass had been added to the usual materials for crown-glass; I cannot otherwise account for the appearance of the lead here. In the last experiment, the lead of the flintglass had been revived.

Experiment V. Two ounces of the same iron, immediately upon being taken out of a retort, in which they had been kept at a red-heat for about an hour and a half, and which were, therefore, as free from water as iron can easily be procured, were put into an earthen tube, unglazed, and closed at one end. This tube was Vol. IX.

disposed as in Experiment II, only the end of the glass tube was immersed in mercury, instead of water. It is not furprifing that air did not now come over fo foon as in any former inftance. When the fire was raifed to its full force, exaftly the same amusing veriety of appearances took place as in the last experiment. Under the pressure of half an inch of mercury, not a particle of air was discharged; but, the moment the pressure was diminished to a small fraction of an inch, the bubbles fucceeded each other pretty quickly; and fo on repeatedly. Upon lowering the furface of the mercury, and pouring fome water upon it, I received more than two ouncemeasures of air, which, by the test of lime-water, did feem to contain a veftige of carbonic acid, but it was too minute to be appreciated. This experiment with the air was made after a ftrong white heat had been kept up for three hours. Soon afterwards the bubbles ceased; but we could not then, nor upon examination of the apparatus when cold, discover any failure. The fire was still kept up for three hours; the tube must have been exposed to a strong white hear feven hours in all. The iron had loft eleven grains in weight: only about one half had been thoroughly fused. The surface of two lumps, that had not been fused, had the close texture, and filvery appearance, of malleable

iron. The thin edges yielded to the stroke of the hammer, and a gentleman perfectly conversant in the nature of iron, agreed with me, that it had all the characters of malleable iron.

Experiment VI Thirty-one grains of artificial plumbago, in thining flakes from the 'iron-works, were expered, in a small retort, to a strong heat, for fix hours, in the same pneumatic apparatus. It was difficult to feparate, even by the help of the magnet, all the intimately-mixed particles of iron; and there were also a few particles of coak incorporated with the plumbago. Air, of an explosive inflammable kind, was extricated, and rofe freely, through five inches of mercury. We had not been fufficiently careful to let the lute fix before we commenced the experiment, and it foon failed. Upon taking off the pressure of the mercury entirely, and repairing the lute as well as we could, we had every reason to believe that the air soon ceased. The air received in the mercury contained oneeighth of carbonic acid: the remainder exploded. The plumbago loft four grains. Mr. Pelletier, if I remember right, found that native plumbygo, exposed to a fierce and long-continued heat, lost 10 grains in 200. In the present experiment, its appearance was unaltered. Probably the lofs was owing to moisture imbibed by Ggg 2 the

the particles of coak, and to a small combustion by the air in the retort.

It will, I think, be admitted, that these experiments abundantly confirm the inferences I had formerly drawn, from appearances by their nature less decifive. The real extracation of air, varying in its nature at various periods of the process, feems to be placed beyond doubt. The experiments in glazed and glass vessels were made with a view to exclude the possibility of the supposition of the air entering through the pores. I think that Dr. Prieftley, if he should repeat these experiments, and find that they have been accurately made, will, with his accustomed openness to conviction, abandon an opinion he has for fome time entertained, and no longer confider water as effential to the constitution of elastic fluids. Several observations might be made upon this point, and those which I have just noticed above; but they will readily occur to perfons converfant in chemistry. I shall therefore confine myself to the unexpected and anomalous appearances, and then attempt to draw a few ufeful inferences.

First. I was surprised at the extrication of inflammable air in such low degrees of heat. We have seen that cast-iron, highly charged with charcoal, (the phlogisto onusum of Bergman,) yields air at the temperature of melting lead.

For.

For, undoubtedly, the blifters of lead, which lay upon the iron, are to be confidered as air-bubbles, caught in a folid film of lead. Perhaps white caft-iron would not yield air fo readily; possibly iron holds its charcoal with more force, as it contains less. I intend to make some comparative experiments upon the varieties of castiron; but so curious an appearance as these blisters will always be rather the bounty of accident than the effect of skill or labour. The obvious method to produce them would be, to cover the iron with lead. All the unmelted lamps of iron were porous, and open in their texture.

Secondly. I am at fome lofs how to explain the occasional discharge and cessation of air, in one experiment, in which a crown-glass retort was used, and in another, with an unglazed earthen tube. There was no flaw in the lute, nor in the veffels, for it was discharged for the space of several hours, under a fmall preffure. Either, then, it was forced through the foftened glass in the first, and the dilated pores of the tube in the fecond case; or it was absorbed by the substance of the veffels; or it was not extricated from the iron. Of these suppositions, the third seems to me the most probable. It is not likely that a hole should be made through the melted glass, under the preffure of half an inch, and closed under that of perhaps

haps the eighth of one; or that pores in the tube should open and shut in conformity to such a variation of circumstances; and, with regard to the tube, there can be no question as to absorption. One principal difficulty, as it appears to ne, in the manufacture of iron, is to get rid of the charcoal. The oxygen readily enough unites with a fmall portion; but the attraction of the iron on the one hand, and, on the other, the little disposition of the charcoal to put on the elastic form, in comparison with many other less fixed fubstances, together form a very confiderable obstacle to the change of charcoal into air; and, as I have already observed, the iron probably holds the charcoal more strongly, as its quantity diminishes. In this state of things, a small additional impediment will prevent the heat from throwing the charcoal into the state of air; and fome degree of preffure must be adequate to this effect; and why may not this point (from which, as you recede on opposite sides, the attraction of the particles of charcoal for one another, or for iron, either shall or shall not be overcome by heat,) have been found in these experiments? The next confideration will both illustrate and confirm these ideas.

Thirdly. A chemist whose notions of iron are derived principally from books, and from the phænomena which are presented by processes not having

having metallurgy for their immediate object, will be apt to confider forme things related above as inconfiftent; the violence of the heat, for instance, and the smallness of its effects; fince even cast iron was not fused in all the experiments. The fact is, when cast iron exposes a large furface, and heat is gradually applied, it proves almost as infusible as malleable iron. Indeed, by the gradual action of heat, it is converted, fuperficially at least, into malleable iron, or approximates towards it; and confidering only iron and charcoal, I believe the fufibility of iron will be directly as the quantity of charcoal it contains. Now, in the experiments I have described, pieces of one, two, and three drachms, and fometimes lefs, were used, for larger could not be inferted into the neck of the retort. In order to avoid this inconvenience in future, I would recommend cylinders to be caft, of a diameter fuited to the mouths of the veffels. This infufible coat would be an impediment to the conversion of the parts below, by preffing upon them: the elaftic fluids either could not traverse the folid furface fo freely as a liquid, or perhaps, as I am disposed to believe, they could not traverse it at all. The malleable skin seems close in its texture, and the porofity of the rest might arise from the generation of just air enough to produce an internal expansion. In the puddling operation,

operation, it is of the most material consequence to keep the mass in constant agitation. Thus the parts are thoroughly blended, the attraction of cohefion is a good deal counteracted, and there can be no pieces hide-bound, if I may fo express myfelf. This last, perhaps, is the greatest advantage derived from the labour of the workman.

Fourthly. I was asked, by one of the most ingenious and profound philosophers of the present age, why I had neglected the action of the atmospheric air, in the theory of the conversion of iron. It is fimply because its action upon the metal feems, in practice, pernicious. I confider its presence as an evil, though a necessary one, according to the present modes of working. I was also anxious to try this opinion by the test of experiment, and we fee it has been fully confirmed. In the last experiment, part of the iron was completely converted; and, in fome others, it feemed approaching fast towards nature, as the manufacturers express it. It is indeed very posfible to conceive a way in which air might be beneficial; that is, if it could be applied fo as to burn the charcoal merely; but, at present, for one grain of charcoal which it converts into carbonic acid air, it converts many of iron into finery cinder; and, as I have formerly fhewn, this is not the way in which iron is actually converted

verted in the reverberatory, and probably not in the finery furnace.

Fifthly. It is impossible to ascertain the principles of any art, without immediately improving the practice, or opening a profpect of future improvement. The preceding observations may ferve to direct attempts to render the metallurgy of iron lefs difficult, laborious, and expensive. For, first, if a quantity of oxygene, nearly sufficient to burn the charcoal, could be chemically combined with the cast-iron, the operation would confume lefs fuel, and would not require fo long a time. It may be worth while to confider, if the . ores of iron containing manganese, owe any part of their value to this circumstance. Secondly. If it could be contrived to apply a fufficient heat to large quantities of iron in close veffels, and at the fame time to agitate them fufficiently, the loss in conversion would not, perhaps, exceed ten in a hundred. Thirdly. The important object of converting British iron into steel, may possibly be attained by following up reflections fuggefted by the foregoing experiments. When the oxygene has been feparated in the form of carbonic acid, there will remain the charcoal and iron, the conftituent parts of fteel. Perhaps the materials. at a certain period of the process, may be so nearly approaching to feel as to be eafily con-Vol. IX. Hhh vertible.

vertible. The mass will contain also a quantity of fulphur, on which perhaps the difficulty of making good fteel from our iron depends. But this difficulty, I am perfuaded, will not be infuperable.

It may be proper to add, that whenever attention was paid to it, the hepatic fmell in the extricated air was perfectly diftinguishable.

I also think it right to say, that whatever information or advantage may be derived from these facts and observations, must be in a great meafure ascribed to the liberal curiofity of William Reynolds, whose enterprising spirit and inventive genius have improved our machinery, enlarged our manufactures, and changed the face of a large diffrict in his native county.

P. S. The refiduum of 486 grains of cast-iron, the same as that used in experiment I, weighed 481 grains, after being diffolved in weak vitriolic acid, and heated to a dull red heat; the fame quantity of iron, after the experiment, afforded a refiduum of 39 grains, and a little more. In the refiduum left by equal quantities of inon, before and after the experiment in the unglazed tube, there was a difference of five grains: the folution of the iron that had been submitted to the experiment went on very flowly, and would

not

not have been effected by vitriolic acid in many months. In the latter case, I used some muriatic acid, which quickly diffolved it: in the former, weak aqua regia was used for the folution of a very small part of the whole lump. I suspected lead to have caused the flowness of the folution in the first case, but there can be no such suspicion in the fecond. The difference between thefe refiduums tends to shew that plumbago was confumed by the heat, but they do not shew the lofs accurately; for, in the refiduum of the iron that had been fuled in the first experiment, there was a fmall quantity of vitriolated lead; and in the other there was, befides the plumbago, a fmall quantity of that difficultly foluble calx of iron, which the folutions of this metal deposit on long exposure to air; the difference was greater, therefore, than it appeared. On the other hand, the long action of the acids might have confumed fome plumbago. There was little or no calx attractable by the magnet in the refiduum of the fused iron. From the 48 grains of refiduum, I feparated more than fix grains by the magnet.

LII. Conclusion of Sir GEORGE SHEE'S Observa-

(From Page 345.)

THE improvements then which I beg leave to recommend in the construction of merchant-vetilels are, an increase of their horizontal, and a decrease of their perpendicular dimensions; which will-correct the three defects I have pointed out; also the alteration in the shape of their sides and bows, which I have already said is necessary, in order to render these improvements practicable.

Were the 'length of the keel even so far extended, as that it should reach two perpendicular lines dropped from the extreme points of a ship's upper-deck, the increase of gripe would be prodigious, and the additional expence trissing. A sheer of projection abast is unquestionably beautiful; but it is of no use, and the eye would soon become reconciled to an upright stern. The sheer, however, might be given with any length of keel, where expence should be disregarded; unless it should be thought, which I am rather inclined

inclined to believe, that a very long vessel would be weakened by it; for the strain upon a ship's centre is in fact resisted more by the binding of her upper planks and timbers, than by the strength of her keel. The expence of this increase of length would be nearly paid, by the saving caused by the reduction of her depth.

The alteration in the form of the fides and bows needs a few words more of explanation.

The effect to be expected from a flat fide is exemplified in an ingenious contrivance, used to supply want of depth, in Dutch vessels of various descriptions; and I cannot give a more correct idea of the improvement in this respect I wish to recommend, than by saying, that the side of a ship, below the water-level, or a part of it at least, ought to resemble a lee-board, of considerable extent. By means of this board, many Dutch merchant vessels, notwithstanding they are constructed with a sloor almost flat, to sit them for great burden and shallow water, are found to sail tolerably well upon a wind; and yet they are in general short, with bluff upright bows, and many other desects.

Dutch fishing-vessels too, particularly those employed in great numbers on the coast of England, are rendered, by the use of a lee-board, good sailers. Not being intended for burden, they do not, in general, much exceed boat-fize; and, although

although they are the most flat of all decked vessels, their security in blowing weather is proverbial.

Now, in respect to the bows of merchant-ships, I will only observe, that although they slope off tolerably well when vessels are light, they prefent, when laden, such resistance to head-way, as can scarcely be overcome by any pressure of fail. The evident remedy is, to render them less upright; expansion in them, although absolutely necessary above the water-level, being quite use-less below it.

By adopting these improvements, I am perfuaded, that the same quantity of timber, and other materials, now employed in building a merchant-vessel of one hundred tons burden, would serve to form one capable of carrying at least one hundred and thirty, and that the velocity gained would rather exceed this proportion. The advantage of performing three voyages in the usual time of two, or even suppose sive in the time of sour, need not be stated; nor need that which would result, in the season of tempest, from reducing the length of time in which ships are exposed to danger; or, in time of war, from seasons them capable of evading pursuit.

The construction of vessels employed in carrying mails between Dublin and Holyhead, I conceive to be nearly as defective as that of mer-

chant-

chant-ships, which their hulls in a great mea-· fure refemble, although they are built expressly for fpeed and accommodation, and not for builden. But indeed they do carry burden; for, from their deep form, they require an absolute loading of ballast, to prevent them from oversetting; and their draught of water is fuch, although small veffels, that they can float on the Dublin Bar only at a particular time of tide; by which, fair winds are frequently miffed, and the paffage from England unnecessarily prolonged. From their want of length, and exceffive depth, they are fuch flow failers, that the Favourite, a light long veffel, fitted out by private individuals, has made her passage to Holyhead in nine hours, when two packets, which weighed anchor when the did. took twelve to perform theirs.

In determining the most proper construction for these, or indeed any other sea-vessels, it should be considered, that the greater the length, the less depth will be necessary to prevent leeway; and that the greater the breadth, the more sail may be carried, and the less ballast required. Weight, it is true, does not operate exactly upon ships as burden does upon animals; its situation, as I have already said, determining in a great measure the resistance it causes to velocity; but, that its operation is considerable, cannot I believe be doubted. In short, I am pursuaded that packet-

packet-veffels might be conftructed on a principle so light, that they might pass the Dublin Bar, at any time of tide, so speedily, that they would commonly perform their voyage in three-fourths, or perhaps two-thirds, of the time those in use now employ; and, at the same time that they would, if possible, be more safe, and certainly much more commodious, their building and failing charges would not be more considerable.

To determine the exact extent to which the improvements I recommend can, in general, be practically applied, is not my present object. I only mean to suggest hints, which, if thought deferving of the trouble, may easily be thrown into a regular system; and I will close an address, imperceptibly extended beyond its intended limits, with a word on ships of war.

If these improvements are founded on the true principles of naval architecture, their application may certainly be extended to the confiruction of frigates, and all other king's ships carrying one tier of guns only; but, that those of two and three tier can be improved in an equal degree, is an affertion I will not hazard. The effect of the weight the latter carry above watermust be counteracted by a proportionate weight below it; and it is possible that an increase of their horizontal expansion would be unsafe, confidering that timber beyond the present dimensions.

fions cannot well be procured. Determinate flatness of fide, however, for some distance below
the furface of the water, would aid very considerably in resisting the effect of a fide-wind, on so
prodigious a surface as their hulls present above
water; and even a very trisling addition to their
breadth of beam would probably enable them to
carry their guns better than they now do in a
high sea, and render some reduction of their
draught of water practicable.

That light frigates might be made capable of receiving as great velocity from a moderate breeze, as is now given them by a ftrong wind, is a truth I am perfuaded of; and that the utmost velocity any vessels are capable of is not yet attained in the European seas, is a fact that will not be doubted by any person who credits the well-authenticated accounts given of slying prows. The form of these vessels, it is true, unsits them for any other sea but that in the latitude of the Ladrone Islands, but useful hints may notwithstanding be taken from their construction.

Vol. IX. I i i LIII.

LIII. Experiments on the comparative Effects of Solutions of Magnesia, of calcareous Earth, and of Alum, in dying Cloths of various Kinds with Madder, &c. By Mr. VOGLER.

From CRELL'S CHEMICAL ANNALS.

Pure magnefia, properly prepared from Epsom falt, (Magnefia Vitriolata,) and thoroughly washed, was thrown gradually into oil of vitriol, into spirit of nitre, and into spirit of salt. Each of these acids quickly dissolved it, (without the affistance of heat,) with effervescence; and the solutions continued clear, until the acid was completely saturated. A portion of the earth then separated, part of which remained suspended on the surface of the liquor, the other part fell to the bottom. None of this appeared capable of being dissolved, either by the addition of more acid, or by the addition of water, or by the application of heat.

Each

Each of the above mentioned folutions of magnefia was diluted with three times the quantity of pure water. Woollen, filk, lines, and cotton cloths, all which had been first clean scoured, and dried, were then put into these solutions, and left to soak therein for the space of ten or twelve hours. At the end of that time they were taken out, washed in three separate quantities of clean cold water; then wrung out and dried.

I now fet over the fire three deep earthen pots, in each of which I put two drachms of madder. and about a pint (from twelve to fourteen ounces) of clean foft water. After they had boiled for a few minutes, I put into one of the decoctions the pieces of famples of cloth, of different kinds, which had been prepared and foaked in the folution of magnefia made with oil of vitriol. Into another, I put those pieces which had been foaked in the folution made with spirit of nitre; and, into the third, I put those which had been soaked in the foliation made with spirit of falt. When these pieces of cloth had boiled therein for the space of feven or eight minutes, (during which time they were frequently turned about and preffed with a · flick,) they were taken out of the decoctions. and, after being two or three times wrung out of clean cold water, were dried in the shade. The Tii 2 wool

wool and filk appeared to be dyed throughout of a bright brown colour; the linen and cotton were of a pale red.

Experiments fimilar to the above were at the same time made with solutions of calcareous earth, in the vitriolic, nitrous, and marine, acids. The colours communicated to the cloths prepared in those solutions, and afterwards boiled in a decoction of madder, were found to differ very little, or not at all, from those obtained by means of the solutions of magnetia.

In the fame manner I found, by repeated experiments, that alum, and the folutions of its earth in the different acids, gave (when used in dying with the decoction of madder) a light brown colour to wool and filk, and a red colour to linen and, cotton. But it must be confessed, that these colours were brighter and finer than those produced with the solutions of magnesia, or with those of calcareous earth.

It appears, therefore, from the above and other comparative trials made with folutions of the aluminous, magnefian, and calcareous earths, in dying cloths of different kinds with madder, logwood, brazil-wood, &c. that no advantage is derived from the use of the two last; as alum and its solutions produce finer colours, and confequently

quently may at all times be employed in preference to the others.

It would perhaps have been worth while to have tried, in the fame manner, the effects produced by folutions of barytes or heavy earth, and likewife those of manganese (when freed from heterogeneous matter) and its calx, in dying cloths of different kinds with the above-mentioned fubstances; but, not possessing a sufficient quantity of the harytes, and not having had time and opportunity to prepare pure manganese and its calx, I have not yet been able to undertake a course of experiments on that fubject.

LIV. Experiments to Shew in what Proportion pure Nitrous Acid is capable of dissolving Gold. By M. SAGE.

From the Memoirs of the Academy of Sciences of Paris.

PURE nitrous acid (of forty-nine degrees, according to M. Baumé's areometer *) has fcarcely any action upon thin plates of gold; for, three ounces of this acid, having been boiled upon twelve grains of gold, in the form of a very thin plate, until the acid was reduced to about three drachms, the plate of gold was found to have diminished in weight only $\frac{\tau}{3.2}$ of a carat.

Three ounces of nitrous acid (of forty-two degrees) diffolved only $\frac{1}{64}$ of a carat of a thin plate of gold.

^{*} To obtain the nitrous acid of this high degree of concentration, I separate it from nitre, by means of vitriolic acid: I then precipitate it by filver, and distil it again several times.

A lump of gold, from which the filver (amounting to three quarters of the gold) had been feparated by quartation, and which had a porous appearance, was boiled in three ounces of nitrous acid, (of forty-two degrees,) till there remained only about three drachms: the gold was found to have diminished $\frac{16}{32}$ of a carat.

Three ounces of nitrous acid (of forty-two degrees) diffolved, of a lump of porous gold weighing twelve grains, only $\frac{3}{2}$ of a carat.

Three ounces of nitrous acid (of forty-two degrees) having been made to boil upon another lump of porous gold, also weighing twelve grains, until the acid was reduced to about three drachms, diffolved only $\frac{3}{5.4}$ of a carat of the gold.

LV. List of Patents for Inventions, &c.

(Continued from Page 360.)

WILLIAM BIRCH, of Charlotte-street, in the parish of St. George, Bloomsbury, in the county of Middlesex, Esquire, on behalf of himself and of his son Richard Comyns Birch, of Calcutta, in the East Indies, Esquire; for a method of purifying, refining, and preparing indigo, for the use of dyers. Dated August 11, 1798.

George Dodgson, of the parish of St. Leonard, Shoreditch, in the county of Middle-fex, cabinet-maker; for a method of making and constructing pumps and engines for raising and evacuating water, or other fluids, and for producing power; and is peculiarly adapted for the use of ships and vessels. Dated August 23, 1798.

FRANCISCO RAPOZO, of Lisbon, in the king-dom of Portugal, captain of engineers in the service of her Most Faithful Majesty; improvements in the construction of steam-engines; Dated August 29, 1798.
